THE Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VII.]

JANUARY 2, 1888.

[No. 73.]

Our Portrait Gallery.

SIR JOSEPH DALTON HOOKER, M.D., F.R.S.

SIR JOSEPH DALTON HOOKER, according to *Men of the Time*, is the second and only surviving son of the late Sir William Jackson Hooker, Regius Professor of Botany, Glasgow University; subsequently Director of the Royal Gardens, Kew. He was born at Halesworth, Suffolk, June 30th, 1817, and was educated at the High School, and University of Glasgow, where he graduated M.D. in 1839. At the age of twenty-one he accompanied officially as assistant surgeon, but in reality as naturalist, the famous expedition of Sir James Clark Ross, fitted out by the Government for the purpose of investigating the phenomena of terrestrial magnetism in the south circumpolar seas. The result of his researches during this voyage was a series of superb volumes "On the Botany of the Southern Regions, embracing the Flora of the Auckland Islands, New Zealand, and Tasmania." He returned to this country after an absence of four years. In 1846 he accepted the appointment of Botanist to the Geological Survey of Great Britain, under Sir H. De La Beche, and he contributed a valuable paper to the second volume of the *Records* of that Institution, "On the Vegetation of the Carboniferous Period as compared with that of the present day;" and another "On the Structure of Coal Fossils." In 1847 he undertook a journey to India, for the purpose of investigating the plants of tropical countries, and the flora of a hitherto unexplored region of the Himalayas. In the course of his travels in these remote districts he was for some time kept prisoner by the Rajah of Sikkim. He returned in 1851, and published two very interesting volumes of "Himalayan Journals," and a number of scientific works "On the Botany of India." In 1850, while in India, he published some beautiful sketches of rhododendrons from the Sikkim Himalaya, several of which have since been introduced into England. These expeditions, though partly at his own expense, were conducted under the authority of Government, which supplied some of the funds. He was appointed in 1855 Assistant Director of Kew Gardens, and

on his father's death in 1865 succeeded to the Directorship, which he resigned in 1885. He was some time Examiner, in Natural Science, of candidates for medical appointments in the Royal Army, and late East India Company's service, and Examiner in Botany to the London University and Apothecaries Company. In the autumn of 1860, with the late Admiral Washington and D. Hanbury, F.L.S., he made a tour in Syria, during which he paid special attention to the oaks of that country. Dr. Hooker presided over the meeting of the British Association, held at Norwich in 1868. He was appointed a Companion of the Bath (Civil Division) in 1869.

In April, 1871, Dr. Hooker left England for Morocco in company with Mr. John Ball, F.R.S., and G. Maw, F.L.S., his purpose being to collect the plants of that comparatively unexplored country. On the 16th May, with his companions, he made the ascent of the great Atlas, the summit of which mountain has never before been trodden by a European, and at the close of June he returned to Kew, bringing a large collection of plants. In 1873 Dr. Hooker was elected President of the Royal Society, and resigned in 1878, when the late Mr. W. Spotiswoode was chosen as his successor. In 1854 he was awarded a gold medal by the Royal Society. In 1884 the Founders Medal of the Royal Geographical Society was awarded to Sir Joseph Hooker for his eminent services in scientific geography; and, in 1883, the Society of Arts presented to him their Albert Medal for the services he had rendered to the arts, manufactures, and commerce, by promoting an accurate knowledge of the floras and economic vegetable products of the several colonies and dependencies of the empire. Sir Joseph is a member of various learned societies, and a corresponding member of the Institute of France. His works are:—"Botany of the Antarctic Voyage," 6 vols., 4to, 1847-1860; "Rhododendrons of the Sikkim Himalaya," 1849-1851; "Himalayan Journals," 2 vols., 8vo, 1854; "Genera Plantarum," 1862, *et seq.*; "The Student's Flora of the British Islands," 1870; "The Flora of British India," 1874; "Journal of a Tour in Morocco and the Great Atlas," 1878.

Original Communications.

ON A NEW METHOD OF TREATING SKIN DISEASES LOCALLY.

By H. VALENTINE KNAGGS, M.R.C.S., L.R.C.P.

II.

EMULSIFICATION IS THE ONLY PRACTICAL METHOD BY WHICH OINTMENTS AND LOTIONS CAN BE DEFINITELY AND PERMANENTLY COMBINED TOGETHER.

IN my paper on the dermatological uses of permanent emulsions I endeavoured to describe a few of the salient features of that particular line of treatment. I now wish to point out the precise methods by which I arrived at my results, and to direct attention to the manner in which the various constituents of these preparations are built up. In order to effect this purpose it will be necessary for me to commence from the standpoint of my original observations, and to then gradually work up from this until the perfected preparation (as I regard it) is arrived at. Three years ago, when I first began to study this subject, the use of lanolin as a suitable basis for ointments was practically unknown, and the importance of mixing water or medicated fluids with ointments was but faintly realised. The introduction, by Professor Leibreich, of wool-fat, with its remarkable power of absorbing water, gave an immense impetus to this important question. At the present time lanolin ointments, ointments rubbed up with water and lotions, and even mixtures of oil and mucilage—the gum-oil as it is usually termed—are quite in the order of the day, and would naturally lead one to suppose that the tendency of modern dermatology is towards the perfect admixture of an oil or fat with water, to which suitable medicaments can be added or required, or, in other words, the permanent emulsion.

My first experiments were made with glycerine and fatty substances, when employed for the purpose of treating a chapped condition of the skin resulting from cold. I noticed when vaseline or lard was rubbed over the hands immediately after they had been washed in ordinary water, or in a weak solution of carbolic acid or perchloride of mercury, that a marked difference was observable, both in respect to the greasy feeling, and also in the appearance of the mixed ingredients on the hands, than when the oily application alone was used.¹

Anyone who has tried, or who will try, these two methods will not fail to be struck with the dissimilarity existing between them, and to observe the superiority of the former over the latter, both as to the time necessary to effect a cure, and to its greater protecting power as a

¹ This fact was evidently known to the Romans, who brought the practice of oil inunctions to a high state of perfection. It was often customary for the Roman bather to be rubbed with oil before entering the bath. This was in all probability done *in order to increase skin action*. The body was further anointed with rare oils and perfumes at the completion of the bathing process. By becoming temporarily emulsified with the cutaneous secretions, etc., it is quite feasible to suppose that these oils, when so rubbed in, produced a feeling of exhilaration; prevented the bather from catching cold; and served the purpose of a protective coating or dressing, thereby *checking any tendency to increased functional activity of the skin*. Prior to this the same process of oil inunction in connection with the bath was also resorted to by the Greeks of antiquity. In Pope's translation of Homer's *Odyssey* the following marked reference to this practice is found:—

“Sweet Polycaste took the pleasing toil
To bathe the prince and pour the fragrant oil.”

dressing, when applied to a diseased surface, or when used for obstetrical and other purposes. When vaseline is employed in this manner, and is smeared over the skin when wet, it combines with the water or medicated solution to form on friction a temporary emulsion.

All the semi-solid mineral and glycerine fats will contain and hold watery solutions, although, when they are melted by the aid of heat, the latter will become dissolved out. The quantity of water held in suspension, however, is strictly limited, the percentage varying according to the consistence of the fat. Generally speaking, it may be said with regard to ointments that the more solid they are, the greater the quantity of water or of lotion they are capable of containing. It is now generally recognized that combined preparations of this kind prove very serviceable, and often answer better than simple ointments, while many of the ointments in common use, such as ung. zinci, ung. hyd. oxidi rubri, ung. gallæ c opio, etc., are often materially improved, both as regards their appearance and increased efficacy, by the addition of water. In preparing these ointments the medicaments should be well mixed with the water, and the resulting paste incorporated with the fatty substance until a more or less perfect mixture results.

An ointment or ointment-basis can of course be equally well blended with watery fluids and lotions locally, by making use of the affected part of the skin in the place of a mortar or pill-tile. The portion of the surface covered by the eruption being first washed with the lotion, is immediately afterwards smeared with the fat, the two applications being then rubbed together until a kind of lather is formed. A troublesome case of eczema of the fingers, which had resisted all efforts at treatment, was the first case that I treated in this manner, by the use of a simple combination of boric acid lotion with vaseline. In a few days the eruption was completely cured, much to my astonishment. I have treated several other cases of eczema in a similar manner and with good results, but I have now finally discarded this method in favour of the permanent preparations which are in every way superior.

Mechanical emulsions of a fatty substance prepared with a gum may be divided into two classes:—

The Temporary Mixture or Gum-Oil, where the fat being merely suspended by mucilage, separates in its original and uncombined condition on standing, and floats to the surface of the preparation. With a semi-solid fat this separation will also occur when the mixture is heated to the melting point of the fat.

The Permanent Mixture or true Mechanical Emulsion, in which the oleaginous body is subdivided into minute microscopical particles, each of which is enveloped by the emulsifying substance. In this form of emulsion the countless particles of encased oil globules float to the surface of the medium in which they are prepared, not as an uncombined fat, but as a creamy deposit; while the lower strata of the compound consist of water, and not of mucilage, as in the former type of mixture. The latter form of emulsion is, as far as possible, a homogeneous basis, and although possibly it may contain exactly the same ingredients as the other, yet to my mind there is as great a difference between the two as between pure milk (where the oil particles are minutely subdivided and surrounded by casein) and a mixture of butter and skim milk that has been temporarily blended by the aid of heat and trituration.

The unmedicated paraffine emulsion is a thick fluid which definitely retains its creamy appearance, and may be

John B. Hooker.

described as the direct and permanent amalgamation of an ointment-basis (paraffine molle) with a boric acid lotion. When a medicament is added to this emulsion, it will be found that the preparation is then composed of an ointment and a lotion. For example, if oxide of zinc be used for this purpose, it will be seen that the compound thus medicated is constituted as follows:—

Paraffine molle, 1oz.		Boric acid, 16 grains.
Zinc oxide, 2 drams	Gum Acacia, 160 grains.	Water, 1oz.
or		or
Ung. zinci oxidi		Boric acid lotion.

It will be observed in this instance that a zinc ointment is permanently blended with the boric acid lotion through the agency of gum acacia, and that the resulting emulsion is a direct combination of the two.

Using with the simple formula the same medicaments as are ordinarily employed in the preparation of ointments and lotions, it is practicable to obtain an extensive range of local applications, which, although their constituents are built up from ointments and lotions, yet have properties entirely different from either. Moreover, where any drug or chemical, which it may be thought desirable to use with these emulsions, is more soluble in oil than in water, it may be dissolved in the mineral fat previous to its incorporation with the other ingredients, or on the other hand substances freely soluble in water may be added to the fluid used to prepare the compound. By emulsification the particles of the fat are brought into combination with the aqueous fluids used in the process, and are so rendered soluble. The ointment or ointment-basis loses its character when so combined and becomes merged in the lotion, or *vice versa*.

We thus possess a basis for the application of medicaments to the skin, which, on account of its adhesiveness, and complete solubility in the cutaneous fluids, affords an efficient protection against atmospheric influences and injury, at the same time that evaporation from the skin is *impeded*, a condition promotive of cutaneous rest, and consequently beneficial in the reduction of inflammatory action.

THE INFLUENCE OF "NIPPING" UPON HEALTH.

By GEORGE HARLEY, M.D., F.R.S.,

EX-PROFESSOR UNIVERSITY COLLEGE, LONDON.

ALTHOUGH the effects of drinking alcoholic stimulants to excess are well known, and have been often commented upon, little or nothing has been written on the influence small quantities of stimulants have on the human constitution, notwithstanding that by far the majority of men truthfully denominate themselves moderate drinkers, and consequently the greater number of one's patients belong to this category. The reason of this is not far to seek; for it requires but a very little reflection to tell us why the profession as a whole know so little about the matter, seeing that at least four tangible reasons at once present themselves to the mind.

1. In no instances are the effects of "nipping" sufficiently severe to necessitate any special form of treatment in a public institution.

2. That its deleterious influences on the bodily functions are so insidious as, in the early stages, either totally to escape detection, or, what is more common, to lead them to be attributed to some entirely different cause.

3. The effects of "nipping" manifest themselves in such a variety of different forms that, even where their true nature is recognised, the general practitioner has not the opportunity of seeing a sufficient number of any one of them to admit of his drawing conclusions from them.

4. The men who have most experience of the diseases directly traceable to the effects of moderate drinking, are in general merely those who, like myself, make liver and kidney diseases a special study—the liver especially, being the organ of the body which is most effected by alcohol when indulged in within the limits of what is called strict moderation. And next to it the three other organs of the body upon which stimulants in small quantities act prejudicially are the kidneys, heart, and brain. The other organs of the body are, comparatively speaking, but little affected by alcohol taken in small quantities at a time.

The value of this statement will be fully appreciated by a glance at the subjoined tables of comparative mortality in different industries, taken from the Registrar-General's report.¹ For, seeing that the average amount of drunkards is much about the same in all industries—when they are considered on such a great scale as over the whole nation—the effects of "nipping," as it is called, are rendered apparent when we compare the tables of mortality in any one or more particular class of diseases of men exposed, in the course of their trades, to the temptation of taking little drops of stimulants at a time and often during the course of the day, with those of men whose vocations do not expose them to be so tempted. The result is as follows. Death-rate of men between the ages of twenty-five and sixty-five exposed to the temptations of "nipping":—

Men exposed to the temptations of Nipping.	Liver Diseases.	Urinary Diseases.	Circulatory System.	Diseases of the Nervous System.
Brewers	96	55	165	144
Commercial Travellers ...	61	44	100	139
Innkeepers, Publicans, Wine, Spirit and Beer Dealers ...	240	83	140	200

While the comparative death-rate of men of the same age engaged in other industries, not exposed to the temptation of "nipping," is in:—

Death-rate of men not exposed to the temptations of Nipping.	Liver Diseases.	Urinary Diseases.	Circulatory System.	Diseases of the Nervous System.
Farmers and Graziers ..	41	31	84	81
Drapers and Warehousemen ...	35	37	75	109
Printers	28	30	93	90
Gardeners and Nurserymen ...	18	39	82	63

The result here shown is startling in the extreme, more particularly as regards the proportions of liver diseases; which the Registrar-General not inappropriately designates as "appalling," seeing that it is in reality six times greater among men exposed to the temptations of "nipping" than in that of all the other industries combined. The actual figures being:—for brewers, 1361; for vintners and other salesmen of wines, spirits, and beers, 1521; and for waiters and barmen (those most exposed to temptation) no less than 2205! Whereas, for maltsters, who are only concerned with the materials from which the intoxicants are manufactured, and not with the intoxicating liquids

¹ Supplement to the Forty-fifth Annual Report, 1885, p. xxxii,

themselves, the death-rate is only 830! Nothing could be more conclusive of the deleterious effects of moderate drinking on the human constitution than this; for everything in this world being but relative, it is easily seen how a lesser proportion of "nipping," though giving rise to lesser results, must nevertheless cause a proportionate amount of cases of disease to those given in the above tables, in the liver, kidneys, heart, and nervous system.

It is not difficult to understand why the liver, of all organs in the body, should be the most affected by "nipping," when it is remembered that almost every drop of alcohol taken into the stomach is absorbed by the branches of the portal veins, is conveyed directly to the liver, and has to filter through its tissues, ere it can get into the general circulation, and by it become distributed to the other organs of the body. Moreover, as I showed so long ago as 1853,¹ the mere injection of alcohol into the portal vein in dogs is sufficient to disorder the hepatic functions to such an extent as to cause the animals to become diabetic in the short space of from two to three hours. The result of the two following experiments prove this. The first is one of the experiments I had the honour of performing at the Collège de France before a commission appointed by the Société de Biologie.² Into the mesenteric branches of the portal vein of a full-grown healthy retriever dog, I slowly injected 16 cubic cm. (half an ounce) of pure alcohol, mixed with an equal amount of water. And such was the effect of this procedure on the glucogenic function of the liver, that in three hours the dog was found to be markedly diabetic. The most rapid example of the supervention of diabetes after the introduction of alcohol into the portal vein I ever met with, was in the case of a small mongrel adult dog. The quantity of alcohol employed being ten grammes, along with an equal amount of water. In two hours this dog's urine contained sugar. A similar explanation of the reason why the excretion of urea is diminished by alcoholic stimulants might be given, seeing that, as Voit and others believe, it is formed in the liver. Vogel showed that when the liver's function is disordered in cases of hepatic cancer, a very small quantity of urea is found in the patient's urine. Voit's idea is that the urea is formed in the liver by the disintegration of the hæmoglobin of the effete red blood corpuscles. The detrimental effects upon the liver's functions of the direct introduction of alcoholic stimulants into its blood-vessels as above described, accounts, I think, for the marvellous effects "nipping" has on the human liver, as revealed by the Registrar-General's tables of mortality above cited.

The effects of "nipping" upon the kidneys are far less potent than those upon the liver. The cause of this is not far to seek, seeing that a quantity of the imbibed alcohol is eliminated by the breath during its passage in the general circulation, through the lungs, and consequently a much smaller amount reaches the kidneys than what passes through the liver. As, however, it falls to the lot of the kidneys to have to eliminate alcohol from the blood, as they do all other liquid substances, it is easy enough to understand why it should affect them, though it is by no means easy to point out the way by which its deleterious action is accomplished. We know of course that not only the kidneys eliminate the imbibed alcohol (for it is met with in urine), but we likewise know that alcohol, as alcohol, saturates the renal tissue, seeing that I and others have

been able to obtain pure alcohol from the kidneys of persons who have died intoxicated, by the simple process of distillation. The only tangible reasons, however, that we as yet possess for alcohol disordering the renal function exist (1) in the fact of its elimination causing them extra work; and (2) that alcohol increases the renal circulation, just as it increases the circulation elsewhere, and no doubt at the same time causes a corresponding increase in the diameter of the renal blood-vessels by engorgement, and consequent pressure on the inter-vascular tissues. This remark upon the increase of the circulation leads me now to speak of the deleterious action "nipping" has upon the cardiac organ, either in the way of inducing it to become diseased in the predisposed, or in augmenting the diseased condition when the heart is already affected. The reason, I think, is not difficult to understand, when it is recollected that small quantities of alcohol potently increase the heart's action, as is shown by the quickening of the pulse and by the dilatation and engorgement of the retinal blood-vessels. To such an extent too is this actually the case, that Nicol and Mossop found that even two teaspoonfuls of absolute alcohol were sufficient to cause congestion of the blood-vessels of the retina.

Lastly as regards the influence of "nipping" on the brain. Notwithstanding that it is the liver which suffers most severely from the effects of mere "nipping," it is the brain and nerves that are most injuriously affected by intoxication; for alcohol, when considered in the light of a toxic agent is a true cerebro-spinal nerve paralyser, as it not alone suppresses every function of the brain, cerebellum, and spinal cord, and paralyse the sympathetic as well, but it induces true coma, ending in death.

The action of alcohol upon the nervous system, when taken in small quantities at a time, and often, is, I believe, two-fold. Firstly, it acts deleteriously by keeping the blood-vessels on the stretch, and by thus engorging them, causes them to press upon the nerve cells and fibres, and not only prevent the proper performance of their functions, but likewise by preventing them being properly nourished, and thus unable to do their work efficiently. The dilatation of the cerebral blood-vessels here alluded to may be inferred, not alone from the tightness and fulness of the head some persons experience after partaking of stimulants, but from the congestion of the retinal vessels seen by the ophthalmoscope. Secondly, by the remarkable power alcohol possesses, of so acting on the pabulum in the blood, as to prevent it taking up oxygen and exhaling carbonic acid, and thereby becoming fitted for the purposes of nerve nutrition, exactly in the same way, though to a somewhat lesser extent than opium does. This is well shown by the result obtained from a series of experiments I performed on the subject some years ago, a full account of which was laid at the time before the Royal Society, and published in its *Transactions* of 1864, under the title of "The Action of Physical and Chemical Agents upon the Blood, with special reference to the Respiratory Process."

The relative effects of alcohol and opium are:—

In 100 parts of Air.	Oxygen.	Carbonic Acid.	Nitrogen.	Vol. at 0° C. and 1 Metre Pressure.
Composition of employed air ...	20.9	0.002	79.038	20.96
With pure ox-blood	10.58	3.330	86.09	14.91
Ditto plus 5 per cent. alcohol	16.59	2.380	81.03	18.97
With pure calf's-blood	6.64	3.47	89.89	10.11
Ditto plus .005 grammes of morphia	17.17	1.00	81.83	18.17

¹"Recherches sur la Physiologie du Diabète Suéré." Compt. Rend. de la Soc. de Biologie, Paris. Vol. v., pp. 59-61.

²The commission consisted of Professors Bernard, Verdeil, Würtz, and Robin.

A glance at this table suffices to show that alcohol, even in the small proportion of five per cent., exerts a powerful chemical effect on blood, so powerful as to entirely derange one of its most important functions—namely, the function of respiration. The alcohol seems to have acted like an asphyxiant, inasmuch as it has not alone diminished the power of the red corpuscles to absorb oxygen, but to exhale carbonic acid, and that too in the same way, though to a somewhat less extent than morphia does. This peculiar chemical action of the alcohol on the blood nerve-pabulum may be thought to give a reasonable explanation of the paralyzing action of alcohol upon the nervous system, seeing that oxidation is the motor power of all vital action, and in direct proportion to its activity are the manifestations of life accelerated or retarded. Every breath we draw, every movement we perform, every thought we think, is but the outcome of the transformation of matter under the influence of oxygen. If then it be true as above shown, that alcohol possesses the power of preventing the constituents of the blood from being properly oxidized, and thereby fitted for the purposes of nutrition, it is easy to account for its producing the chain of neurotic symptoms already enumerated, terminating in coma and death.

CHOLERA: A PRACTICAL STUDY, AS WELL AS A PERSONAL EXPERIENCE.

BY BRIGADE-SURGEON W. CURRAN, A.M.D. (RETIRED).

(Continued from page 552, Dec., 1887.)

As to that barbarous measure, so beloved of the native practitioner—the actual cautery¹—I have never seen it used, and I am no advocate for a resort to measures in the case of outsiders which I would not inflict on friends or submit to myself. When this disease appears, however, in an epidemic form, in any city or cantonment, the best, or, in short, only

effectual remedies are isolation² and flight. Defoe emphatically says, in his “History of the Plague,” p. 175, that “the best physic against the plague is to run away from it,” and I have sometimes thought that this would also, were it always practicable, which, of course, it is not, be the best physic against cholera. But the former is not always practicable either at home or abroad, and as to the latter, which would appear to have been inaugurated with success by Aurungzebe,² there can be no doubt but that Sir Hugh Rose’s plan—viz., that of camping out, or rather “dodging cholera,” as the soldiers call it, has done more to arrest the progress of this disease and diminish its destructiveness than any other measure we are acquainted withal. Nor is even this without its drawbacks, as so many regiments, or their records, could testify; and I have heard of scenes or sufferings in some of these that would almost tempt one to say that the game was scarcely worth the candle, while not a few have hinted in my hearing that the remedy was, in their cases at least, little if anything better than the disease.

I have already described one visitation of this kind; let me glance at the system from another standpoint, and enumerate some of its drawbacks. If I may judge by my own not very limited experience of these camps I should be disposed to pronounce in their favour; but then that all-pervading element, the weather, happened, though sultry, to be mild and equable on each of the occasions on which I was “out.” The absence of rain prevented that saturation or rather soakage of the surface that is so dispiriting, as well as disagreeable; and the early cessation of the disease amongst us rendered frequent change unnecessary.

When the rain pours down, however, as it so often does in torrents at these times, and turns the loamy surface into a sea of mud, things begin to assume a very different complexion. Then the dripping tent and the sodden floor, the difficulty of drying the clothes and the bedding, of cooking food, or even of standing about without inconvenience, irritates the temper and induces a spirit of discontent and despondency. Add to this the querulous wailing and other unpleasantnesses incidental to ailing juvenile or infant life, within the four

¹ “Wolff,” says Dr. Cooper (“The Travels and Adventures of the Revd. Joseph Wolff, D.D., etc.,” p. 449) “the natives have a remedy which has very frequently succeeded in stopping the cholera, and this is putting a hot iron upon the stomach; and he added, ‘Will you submit to that?’ Wolff said ‘Yes!’ He then branded Wolff three times upon his stomach, which (God be praised!) stopped the cholera, and Wolff began to sleep.” And “the remedy upon which even Europeans relied, in the early days of our settlement at Bombay, was, according to Anderson (‘The English in Western India,’ pp. 132-3), of a painful and barbarous character. A hot iron was applied to the ball of the sufferer’s foot; if he winced it was expected he would recover, but if he showed no signs of pain he was given over by his medical attendants.” He quotes, in a note to the above, a Father Martin as writing in the *Lettres Edifiantes*, tome iv., to the effect that a “Signor Mancuchi . . . had discovered another cure by which he gained vast reputation at the Mogul Court. His infallible remedy was this: Take an iron ring about an inch and a half in diameter, and thick in proportion. Then heating it red hot in the fire, extend the patient on his back and apply the ring to his navel, in such a manner that the navel may be as centre to the ring. As soon as the patient feels the heat—which must necessarily be in an instant (I should think so!)—take away the ring as quickly as possible, when so sudden a revolution will be wrought in his intestines that his pains immediately cease.” Fryer observed (“Account of India,” p. 315) of the Indian physicians of his day that “they apply cauteries most unmercifully in a Mordisheen, called so by the Portugals, being a vomiting with a looseness: the like is done in a calenture.” Dr. Granville treated Lord Palmerston (“Autobiography,” vol. ii., pp. 262-3) for what he called cholera by placing “a long band of thick flannel, four inches wide, over and along the spine, from the joint in the back of the neck down to the upper portion of the sacrum. . . . Over this band he passed lightly up and down a heated flat iron, such as is used in laundries,” and, strange to say, he was not even offered for this “cure,” *alias* this piece of “Priggian” titivation, or tomfoolery, the honour of a knighthood.

² “Clement VI. was so convinced,” says Hecker (“Epidemics of the Middle Ages,” p. 29), of the salutary effect of seclusion that, during the plague in Avignon he kept up constant fires and suffered no one to approach him.” And another case in point is mentioned in a now very rare book, called “Londiniana, or Reminiscences of the British Metropolis,” by Edward Wedlake Brayley, vol. iii., pp. 212-14, which is so curious, not to say so suggestive, that I cannot refuse myself the pleasure of quoting it here. The tradesman here referred to “had a wicket made in his door to take in or send out anything he thought fit. . . . He made it a standing rule that the door should not be opened on any account—fire excepted—and, . . . whenever the wooden window was opened, he caused a flash of gunpowder to be made in the room so as to fill it with smoke.” He also “laid in a seasonable quantity of wines, cordial waters, and brandy, and, in fine, nothing was wanting that the situation he was going into could probably require. His letters were brought to the porter who smoked them with sulphur and gunpowder; then opening and sprinkling them with vinegar, they were drawn up by the pulley and then smoked again with perfumes. The master, taking them up with a pair of hair-gloves, the hair innermost, read them with a large reading glass at a considerable distance, and as they were read burnt them.” He escaped, and as a thanksgiving offering for the preservation vouchsafed him, he “bestowed upon the poor in his neighbourhood the surplus of his provisions, amounting to 1,500 lb. of bread, five hogsheads of beer, 300 lb. of cheese, five flitches of bacon, and some barrels of salt beef and pork.”

² “Grant Duff’s History of the Mahrattas,” vol. i, p. 357. See also in the same direction “Fryer’s Account,” as above, p. 156; Hazlitt’s “History of Venice,” vol. i, p. 245. Mr. (now Sir James) Picton mentions also, if I mistake not, an instance in point in his “Memorials of Liverpool.”

corners of a reeking tent, and you have before you a picture of wretchedness and discomfort for which it would not be easy to find a parallel elsewhere. 'Tis then that the disease finds fitting subjects for its onsets; 'tis then it carries all before it by assault, and 'tis then, too, that

Each diligently bends
Towards common thoughts and things for very fear,
Striving their ghastly malady to cheer
By thinking it a thing of yes or no
That housewives talk of.

Woe be to the man or the woman either who happens to be seized under depressing sights or scenes of this description. He or she will almost certainly succumb under such surroundings, and some of these "casualties" are undoubtedly due to that indifference, I might rather say that weariness of life, that associations of this kind are everywhere so apt to engender or provoke.¹

Some one may here interpose and say, "If such are your views of the situation; if, as you admit, you have nothing tangible to say about it, why write at all on the subject? Or, if you must needs 'deliver your soul' by writing, why do you do so in this gloomy spirit and despairing strain?" That, good reader, is just the question I have asked myself a dozen times at least since I began this little essay. And yet methinks that, though I have no brand-new theory about, or even any infallible remedy to suggest for it, I know as much about it as my neighbours—as much, even, perhaps, as some of those "commissioners" who lately went first-class at your and my expense, to Rome, and who came back with their fingers in their mouths and a long-winded report in their pockets, which will either be pigeon-holed in some Government office, or published in some dreary blue-book that no one will read.

Is not this, or rather, has not this been the end or outcome of all these costly confabulations; and are we any whit nearer a solution of this mystery—for such it undoubtedly is—now than we were fifty years ago? I say deliberately we are not; and I say further that the time has, in my humble judgment, come for us, individually and collectively, to clear our minds of cant and illusion, and acknowledge the limited range of our faculties. Better this than waste our time in cadging about in this way after a cause that has hitherto evaded, nay, mocked at our search, and that may, for aught we know to the contrary, be either a combination or a compound one. Anyhow, no one condition more than another has yet been proved to be so specifically and unequivocally at the bottom of this mischief as to exclude all others; and this being so, would it not be as well to cry Halt for the present, and "recognise the impos-

¹ Based on various information, public and private; and the corps chiefly referred to are the 1st Royals, at Nusseerabad; the 35th, at Agra; the 36th, in the Peshawur Valley; the 51st at Meer-Meer; the 52nd, at Gwalior and Jhansie; the 58th, at Allahabad; about which Dr. Ambrose has written so well, and the grave-yards of India tell tales of this kind which it is impossible to ignore. Mr. McCrae assured me that he buried eighteen men of the 36th one evening at Peshawur; and I copied the following myself off a memorial stone at Meerut, that commemorates the loss by this disease—chiefly, I think, in camp—of the "Buffs":—"To the memory," etc., "of—officers, 2; colour-sergeants, 3; sergeants, 3; corporals, 6; drummers, 14; men, 111; women, 16; children, 43." Nor have these conditions escaped the notice of others. Dr. Munro alludes to them. After mentioning that "within twenty-four hours the command of the Regiment developed upon four different officers," he adds that "here (in camp), too, it was that all, with scarcely an exception, laboured under the influence of choleraic poison, or, at least, sensations not only peculiar, but in many instances distressing," and had rain supervened at this time the situation might have been terribly, perhaps irremediably, complicated and emphasized.

sible—the unreasonably difficult?" It may disappear in time like its mediæval congeners, and make no sign. If so we will bid it God-speed, and ask no questions. *Solvitur ambulando* is not, after all, a bad way of settling difficulties of this kind; and if that country is to be congratulated that has no history that art may assuredly rejoice that has witnessed the decay and survived the burial of its worst, or least accessible enemy.

"It is a favourite subject of declamation," says Dr. McKinnon, "to decry filth and smells as the sources of fever, but there may be fever without filth or smells, as there may be filth and smells without fever;"² and if you substitute cholera for fever here these words will apply to the one as much as they do to the other. Speaking for myself, I would say at once that so far as my observation went on the spot filth and smells had little or nothing to do with either the origination or the diffusion of this disease, and that if it kills most people where these do most abound it is because there are more people to kill off there than there are in more favoured regions.³ A very similar remark will apply to the agency of water in the causation or prolongation of this disease. I saw no instance of its operation in either of these directions that could stand the test of a rigid scrutiny, and if contaminated water is the cause of it I do not understand how it can be absent at any time from the plains or cantonments of India.³

¹ "Annals ut Supra," No. 5, p. 136; and he might have added, with the character in Beaumont and Fletcher's *Prophetess*—

Nor is cleanliness (always)
A saving antidote to keep one from
This deadly poison.

² Depreciating the regret that was expressed by a friend of hers about her returning to town during the prevalence of this disease, Mrs. Sarah Coleridge says ("Memoir and Letters," p. 315) that "I, for my part, believe that the cholera atmosphere is all over England, and that the complaint kills off most people where there are most people to kill, and in the most unfavourable circumstances in regard to diet, clothing, and the air of their dwellings;" and this is, in sum, the view I have been urging all along.

³ Dr. Furnell, of the Madras Army, has written a letter and a book since these sheets were placed in this printer's hands, in which he advocates the water-pollution theory of the propagation of this disease. Others uphold similar views, and the instances of the Broad-street pump of 1854, as well as of the East London outbreak of 1866 are familiar to all. These occurrences are said by some "to be decisive in English opinion as to the water question," and its relation to the diffusion of this disease. Be it so, I will not now argue the question, or even go into any detail—controversial or otherwise—on the point. All I here mean to do is to mention a few facts, ask a question or two anent these, and then leave my readers, as is my wont, to draw their own conclusions. There are, according to all accounts, upwards of two hundred millions of souls in Hindustan, and it is well known that water is the only succedaneum for paper, earth, etc., these use "for their occasions." There are no closets—so far as I could see—anywhere outside the Presidency or other large towns, and yet it is notorious that the tanks, the reservoirs, and the kutchas (unbricked) wells that surround the country villages are freely resorted to for natural purposes by the inhabitants. Moreover, several of the rivers of that country, and notably so the Ganges and the Godavery, the Jumma, and the Nerbudda, etc., are sacred, and it is well known that the water of these streams is carried for ceremonial or sacrificial purposes to every Hindu house in Hindustan. Aye, and far beyond it, and yet, good reader, the country is not depopulated. Far from it, indeed, the soil is thickly, densely in some quarters, populated, and there are scores, nay, hundreds of your countrymen in that quarter who never see a case of cholera. Does this not strike you as, at least, odd, or does it not occur to you that if polluted water were the cause, the originator and diffuser of the disease, the Punjab and the Deccan would have been long since shorn of their fertility and turned into howling Gobis and Saharas? But then this theory meets, it is said, so many difficulties, it solves so many heretofore insoluble riddles that we ought for this, if for no other or higher reason, to accept and admire it. Be

Human agency meaning thereby migrations of human beings, or importations of diseased articles of bedding or clothing¹ from "infected" areas, have been so frequently coupled with the introduction of this disease that it would be presumptuous in me to question it. I think, however, that whenever there is a proper disinfecting or cleansing apparatus available, those articles only should be destroyed that have come into direct contact with the body, or that have been saturated with the discharges. Fire is, in either case, the best solvent, and in no disease is cremation more called for than in this. That experienced veteran, Dr. John Murray, described the disease as "spreading (in his day) like a wave over the Punjab and the North-West, generally along the line of commerce;" and Dr. Cayley looks upon the pilgrims as its "chief carriers" in Orissa. This is the prevailing opinion of all those observers of its movements I have conversed with in the East, but it sometimes ignores these media or anticipations, and advances or recedes irrespective of them as best suits its own sweet will or convenience.

There is, in either case, no occasion for a resort to that old fond illusion of our fathers, the "Angel of Death," or the "Wings of the Wind" theory. Neither need we assume that the malady is conveyed by contagion or infection in the ordinary acceptation of these terms, and I saw no instance at all in which a seizure could be justly said to "depend on the agency of touch, or on an atmosphere tainted by emanations from the bodies of the sick."

This is, after all, it may be said, but a very "lame and impotent conclusion." Be it so, I can offer no better. I can neither explain the inexplicable, nor draw "conclusions" from the clouds. All I can say is that I have "sat by the cradle" of more than one outbreak of this disease, and "followed its hearse," and that, in my humble opinion, no amount of Macdougall's powder or carbolic acid, no sanitary cordons, land quarantines, lazarettoes,² or even cholera commissions will stop the progress—once 'tis on the move—of a disease that has passed as easily over the peaks of the "frosty Caucasus" as it has over those of Devalagiri and

it so, again I say, these gentlemen have just as much right to their opinions as I have to mine, and several of them had far wider fields for cultivating or forming these than I had. All I claim is that I have studied the question to the best of my ability on the spot, and that I came to the conclusion, through that study and that judgment that God gave me, that there is just as much relationship or connection, and no more, between cholera and contaminated water as there is between a hawk and a hand-saw, or better, perhaps, between the Goodwin Sands and Tenterden Steeple.

¹ "I have known cholera to be communicated," says Dr. Richardson ("Diseases of Modern Life," p. 458), "by the clothes of the affected person to the women engaged in washing the same;" and there are several allusions to this subject in connection with the outbreak of 1831 in the "Greville Memoirs at Supra," vol. ii., pp. 157, 193, and also 216-17; as well as in the "Sanitary Departmental Reports" passim.

² Dr. Cunningham has effectually demolished this fgment in his "Twelfth Report" for 1875, p. 48, and, I dare say, subsequently. "The persistence," says Dr. Munro, "with which the disease hung about the regiment, its complete disappearance so often, only to return again with increased violence, even though, to endeavour to avoid it, we vacated building after building in which it appeared," was very depressing; and readers of Kinglake's "Invasion of the Crimea," vol. iii., p. 21, will remember that "the cholera had proved to be a pestilence which was not to be warded off by the stir and glory of battle." He adds in a note that "Captain D'Acres and his captain of the fore-castle alone took out from the tents the corpses of twenty-eight men who had died of this disease during the night," after the battle of the Alma, and any one can surely see from these facts that cholera is a disease, *sui generis*, that recognises no other master but its own sweet will and pleasure, and that will not be gainsayed in its course.

Mount Everest, and that slays as vigorously on the frozen shores of Kamskatka and Labrador as it does on the Coromandel coast, or even at the Soonderbunds, near Chittagong.

This being so, it only remains for me to renew my expression of distrust in the use of drugs in the advanced stages of this disorder, and ask the reader who has accompanied me thus far, to look elsewhere for his remedy. This remedy lies, if I have not misinterpreted the records before me, in (1) endeavouring by all the means in your power in preventing the attack; (2) in nursing it well when it comes. The hot bath and recumbency in a warm bed followed by some carminative or astringent draught will conduce towards the attainment of the former object, for in no complaint is the advice, *principiis obsta sero medicina paratur*, so valuable as it is in this, and in no other illness is good nursing so necessary. To this we must look for such "cure" as is attainable in this malady, especially so in its algid stage.

A distinguished countryman of mine wished that it should be recorded on his tomb that he "fed fevers." If I might presume so far, I would advise you, good reader, to take up a similar view of your responsibilities in this respect, and act on the motto "he nursed cholera." Do not, my friend, allow calomel or other nauseous compound of that description to stick to the tongue or teeth of your helpless patient; and do not, in obedience to any fantastic theory, allow him or her to be scoured on or off the close-stool into eternity through castor-oil, or other drenching stuff of that kind. For 'tis the purging, like the pace, that kills; the vomiting is, comparatively speaking, of lesser consequence. Let him or her have your best sympathy, as well as your kindest encouragement, and do not withhold from either in their agony that harmless drink he or she most covets. Remember further, that though the attack may not kill straight off, it paves the way for such a state of debility or reaction as necessarily implies a lingering convalescence, if it does not actually endanger human life. He alone, in my opinion, will best combat this latter condition who knows best how to stay his hands betimes, or who trusts most to the regulated powers of nature.

APPENDIX.

As the papers quoted below confirm in the main the views propounded by me in this essay—while they have come to hand after it was written—and I am anxious that it should be as complete as possible, I will reproduce them in full, and allow them to speak for themselves in connection with it.

I.—Mr. Lawrence (who was at the time here referred to an officer in H.M.'s 51st Regiment) assured me subsequently—and I am transcribing his own words—that the marching out of his corps, on the occasion of its terrible visitation of 1861, rather aggravated than diminished the helplessness and despondency of its members. Many of the men, he assured me, threw down their arms or accoutrements on their slow march from Mean-Mear to Chebale, from sheer inability to carry them, and some of them even lay down by the wayside to die. He assured me that several women and children died of exhaustion in the doolies that carried them, and when rain came on all these sufferings were enhanced, while others were added to them. He added that the cholera first made its appearance among the men of the company that was stationed in the Artillery lines, and that the authorities brought these into the midst of the healthy men, instead of sending them out at once into camp, as they ought to have done. The disease was in this way diffused in the barracks, and he had also an impression that the drinking water was—or rather, might have been—contaminated with feculent matter by percolation from a neighbouring closet. He could find no other or adequate cause for such an explosion as this was.

II.—Answering some questions I put to him on the subject, Dr. J. J. Clarke, of the Bengal Army, wrote to me as follows at Peshawar, in 1868:—"A severe thunderstorm burst over the encampment of the

pilgrims at Hurdwar (three millions in number) on the night of April 11th, 1867, and cholera made its appearance among them on the following afternoon. Before the 11th the camp was supposed to have been free from the disease. I am induced to think that a cycle of choleraic air struck the pilgrims—not that the seeds of the disease lying dormant in the ground of the encampment were vitalised by the rain. Epidemics in this country go very far to shake one's faith in the contagious nature of the disease; and they would, I believe, even tend to establish the theory of its non-contagiousness. The experiment of 'encamping out' was, so far as this valley (Peshawur) is concerned, rather more of a failure than a success in 1867. I do not despise quarantine, because I believe that great *indirect* good may arise from it. There is not a vestige of evidence, in my opinion, to prove that cholera was imported by the pilgrims into this garrison last year. I have made much inquiry on this point in the city. I have examined police records, and had much conversation with Hukeems (native doctors), and I believe that this garrison was struck by the disease just as the pilgrims themselves were struck at Hurdwar. The disease did not *creep* into the valley; it struck the Europeans in cantonments first, and the blow came down like a sledge-hammer, suddenly and fiercely, upon the Artillery and the 42nd Highlanders the same day."

III.—The following remarks were embodied by myself in one of the statements I had to prepare for the authorities of my department, but it was withheld at the last moment to save an interminable correspondence on the point, and also because it might possibly be regarded as in some measure a censure upon the organisers of this system:—"This would perhaps be the proper place to allude to that plan of camping out during epidemics of cholera which was recently introduced by Sir Hugh Rose, and which has been so much acted on of late years in this country. I intended discussing the subject in some detail, but that this paper is long enough already, and that, moreover, a late judicious general order has so modified the situation as to deprive it of much of the worry and unpleasantness that formerly attached to it. The obligations of frequent, if not, indeed, daily change which the first order seemed to imply rather than enforce has been dispensed with, and the discretion of the commanding and medical officer has been relied on instead. The principle was good, but as in all similar instances of supposed panaceas, the details of it were worked to death, and the families were so harassed in many instances that they hated the very name of the thing. No wonder, for they sometimes lost all their bedding or other belongings, and endured such other inconveniences as can only be realised by him who has witnessed them on the spot. Among these must be included the loss of several children by meningitis or marasmus, and I believe myself that sunstroke and dysentery have numbered more victims under this system than they have ever done in this country before."

IV.—As the question of inoculation for cholera may again crop up at any moment, while the following letter alludes also to a danger from cholera—viz., live burial, that has not been sufficiently dwelt upon, in my opinion, by systematic writers, I subjoin it, and leave it to speak for itself:—

INOCULATION FOR CHOLERA.

To the Editor of the St. James's Gazette.

SIR,—With reference to Dr. Murray's letter on this subject in your issue of the 15th inst., allow me to say, as the result of my own personal experience on the spot, that one attack of cholera forms no protection against a second seizure or recurrence *de novo* of this disease in the same subject. Proofs in point may be easily procured. More than one case of the kind occurred within the sphere of my own cognizance, and one of these especially made such an impression on me as I am not likely to forget. The man in question belonged to the elephant battery, a portion of which is fixed at Peshawur, and he acted as my own orderly during the time that I was attached to the hospital of that corps (the Royal Artillery) at that station. He assured me several times, and others confirmed this statement—it was, indeed, generally known there—that he had been sent on a previous occasion, and as the result of a seizure like that of which he subsequently died under my care, to the local dead-house, to await, along with other corpses, his turn for interment. When the attendants came to remove the bodies on the following morning, they fancied they noticed, as they were lifting him into his coffin, some signs of life in him. They sent for the apothecary of the day, accordingly; and this officer, having employed the necessary measures (including friction and brandy), had the satisfaction of so far restoring him as to be able to order his return to bed. He died, as I have just hinted, of a second attack under my care; and you are, of course, aware that *post-mortem* muscular contractions—some of which closely simulate life—are commoner after death in this disease than, if I except yellow fever and one or two others, they are in any other that science is acquainted with.—I am, Sir, your obedient servant,

August 16th, 1885 (?)

W. C.

P.S.—I may add that, as the result of this and other similar experience of this disease in its home, I am entirely opposed to inoculation as a prophylactic or otherwise against cholera. The process is, in my humble opinion, useless, dangerous, and deserving of nothing but reprobation and censure.

V.—Dr. Pringle's valuable experience of this disease has been laid before the profession since this paper was written, and I was more than gratified at finding, on perusing his paper, how entirely we agreed as to its leading features or peculiarities. I can testify, from personal enquiry and observation on the spot, that cholera has never appeared at Mussoorie or in the neighbouring hills except when it was imported into them from the plains, and his views as to the dispersion or diffusion of cholera by the pilgrims from Hurdwar in 1867 and 1879 accord with those generally entertained on the point in India. His emphatic condemnation of sanitary cordons and land-quarantine is worthy of all acceptance. So is his belief that cholera "is most certainly neither contagious nor infectious in the strict sense of these terms;" and as to his remark that "nursing is the sheet-anchor in cholera, and should be persevered with . . . till death has undoubtedly claimed its victim"—have I not said the same thing over and over again, or acted on the principle involved in it, throughout my whole career? His story of the soldier who "had been put with a pickaxe and a spade into a stretcher, to be buried at the next halting ground," but who was found sitting up when his comrades came up for this purpose; as well as that of the Bengal civilian—still alive—who "heard the order given for his coffin," supports my experience as above, and I quite think with him that "dead-houses (in and out of India) could tell (even) sadder tales" than these. But I cannot, for obvious reasons, continue this criticism. I will conclude, accordingly, by observing that he too insists, like myself and others, upon the occurrence of certain atmospheric conditions as "among the conditions necessary for the development" of a seizure or outbreak of this kind; and he assumes also, like myself and many other observers of the vagaries of this malady, that where these conditions are present "every effort may, and in many cases will, fail to keep out the disease."

VI.—The following remarks, which relate to the manner in which this disease is conveyed or propagated in the "Hills," are from the pen of that experienced traveller and pioneer, the late Frederick Wilson, *alias* "Shikari" Wilson, *alias* "Mountaineer," whose "strange eventful history" and painful death I have glanced at in the *Lancet* of April 24th, 1886, p. 808. They will explain themselves:—"In the spring of 1875 I was (says my friend) in the Deyrah Dhoon, and had a lot of hill men with me. One came from his house in the interior (in April, I think) to see his two brothers, who were in my service as chuprassie and bearer (messenger and valet). He remained with our camp about a week, and then accompanied us to Mussoorie. A few cases of cholera had occurred at Deyrah and Rajpore, and two days after reaching Mussoorie this man was attacked and died in the local Dispensary Hospital five days after admission. One of his brothers had nursed him while under treatment, and after the man's death he and the other brother went to their home in the hills, which they reached in four days. Three days afterwards the younger brother, who had been the nurse, was attacked with illness, and died six days after. The family was a numerous one, consisting of some fifteen members, and two more of them were attacked and died, but no others in the village. In the meantime cholera had been severe in Deyrah and Rajpore, particularly so in the latter place, and many deaths had been the result.

"As usual at this time of the year, when people are going uphill daily for the season, a great number of Puhâries (hillmen) had congregated at Rajpore as porters, and when deaths became frequent, most of them left, and went to their homes in the interior. Many of these men were attacked with cholera on the road. My son, who left Mussoorie for Gangoutree at the same time, saw five corpses on the pathway's side during his three first marches. One of his men was attacked, and cured with camphoriva. Others of those who came from Rajpore were attacked after reaching home, and a few of the inhabitants of the valleys in which they resided were also seized; but the disease did not spread to the other villages in the neighbourhood, and this, too, though these latter were not only very dirty, but they were also hot and sultry. We may conclude, therefore," he continues, "that there is something in the surroundings of this part of the Himalayas that is highly antagonistic to the spread of cholera;" and we may also, I think, admit so far, but no farther, that this disease is at times, and under favouring circumstances, thus conveyed by human agency. How that "conveyance" is effected—whether through the clothes, the breath, the skin, or the excreta—I do not know, neither does anyone else, and having thus exhausted my own stock of personal views or reminiscences of this subject and situation, I withdraw from both, and leave my readers to draw from these such inferences or conclusions as appear best to themselves. *Val.*

THE SANITATION OF CAIRO.

BY DR. GREENE PASHA,

DIRECTOR SANITARY SERVICE, EGYPT, ETC.

CAIRO, according to the census of 1882, has 374,838 inhabitants, as follows:—

Natives with fixed habitations	352,416
Bedouins, semi-sedentary	772
Europeans	21,650
	<hr/>
	374,838

The death-rate per 1000 is thus returned:—

1880	46.02
1881	39.74
1882	47.92
1883	63.98, cholera.
1884	45.39
1885	49.76
1886	47.22

It is needless to point out that these figures represent an excessive mortality; but on the other hand it must be noted that the population is generally thought to be understated in the census, in which case the apparent death-rate should be lowered in proportion to the increase of population.

The subsoil of Cairo is composed of alluvium to an unascertained depth, through which, when the Nile is high, the water percolates to within a foot or two of the surface, flooding cess-pits and basements, and converting all depressions into stagnant pools. There is little or no fall in any direction, so the problem of adapting any system of sewerage is one of exceptional difficulty. At present five separate and distinct sewers of modern construction exist in Cairo. They are distributed as follows:—

1. Ismailia Quarter, ending in the Ismailia Canal.
2. Abdine Quarter, ending in the Khalig.
3. Sharia Mehomed Ali, northern half, ending in the Khalig.
4. Ditto ditto southern half ditto.
5. Ministry of Finance, ending in the Nile.

The whole of these sewers, therefore, are intended to discharge their contents into the only source of water supply in the country—*i.e.*, the Nile and its derivatives. This, in principle, is entirely unjustifiable, and alone should suffice for their utter condemnation as drains. As a matter of fact, however, owing to faulty construction, absence of means for flushing, fissures in the masonry, and unauthorised communication of house drains, these so-called sewers and the soil surrounding them have attained such a degree of foulness as to render them veritable "*foyers d'infection*," as well as the source of the noxious smells that exist perpetually in their neighbourhood.

Besides these modern sewers, there exists also a large number of ancient conduits, whose course is entirely unknown, but which are constantly come across when foundations for houses are being dug. When this occurs, the "fortunate," proprietor immediately makes use of the pre-historic drain as a cess-pit, and thus recklessly runs the risk of poisoning not only his neighbours, but even, it may be dwellers at a considerable distance.

The five modern sewers above mentioned provide for the removal of sewage from a very small portion only of Cairo, for in the vast majority of houses cess-pits for reception of the night-soil exist. A few of these cess-pits are constructed with walls of impervious material, and are situated outside the main walls of the houses; but the greater number are simply holes dug in the ground, occasionally lined with porous masonry, but never floored,

and for the most part placed either entirely or in part *within* the buildings. Owners of houses advance as a reason for this atrocious system, that cemented cess-pits get full too quickly and require constant emptying, whereas if left uncemented, the sewage sinks into the ground, and is thus got rid of without trouble. Moreover, say they, to clinch the argument, this is the system that has always existed, so why should there be a change?

It is, I think, an admitted fact, that of late years the climate of Cairo has undergone a great change; that the air, instead of being extremely dry, is often—especially in winter—excessively moist. Into the causes that have led to this change it is unnecessary here to enter; what concerns us is the fact that owing to this humidity the soil no longer has the power of oxidising, and thereby rendering innocuous, the organic matter of sewage which it formerly possessed. The subsoil surrounding uncemented cess-pits has thus become surcharged with putrifying animal matter, to an extent which cannot but re-act on the public health, and which in my opinion has been the cause of the late widespread epidemic of ephemeral fever, a fever happily of slight pathological importance on this occasion, but of vast significance as a warning of what we may expect should prompt measures not be taken to obviate its return at an early date in an aggravated form, or even perchance in the shape of a pestilence. The more modern houses in Cairo have had a system of water-closets engrafted on to the old established cess-pits. Nothing could well be more insanitary than this, for the more fluid there is used, the more danger there is of soil contamination; and moreover, through defective trapping and absence of ventilation, the chances of sewage gas escaping inside the house are immensely increased when closets are multiplied all over it, instead of being relegated to the most out of the way corner.

There are in Cairo about 282 mosques, to most of which are attached public latrines. These latrines are, without exception, constructed on defective principles, and such of them as do not drain into the Khalig or Nile, are connected with percolating cess-pits of the worst type. In the interests of public health it is the absolute duty, I respectfully maintain, of the authorities to take the necessary measures for remedying this evil.

What is generally considered the most insanitary thing in Cairo is the Khalig, which runs through the most densely populated portion of the city. It consists of a narrow cutting, about 6,000 yards long, and, except at high Nile, is nothing better than a stagnant ditch, into which numberless short drains from mosques and private houses discharge their contents. In the summer the Khalig becomes completely dry, except in a few places where filthy pools remain, being fed by the above-mentioned drains. As soon as the Nile reaches a certain height, the Khalig is filled by the cutting of a dam, all debouching drains having been ordered to be previously hermetically closed. The resulting stream is allowed to flow for a few days, and when all the accumulated filth of the previous seven or eight months is supposed to have been swept away, the inhabitants fill their tanks, and thus lay in a supply of water to last them till the next high Nile. This is the theory; but as a matter of fact the debouching drains are not hermetically closed by any means, and as long as water remains in the Khalig—even though stagnant—the poorer inhabitants, who have no tanks to fill, resort to the Khalig for their daily supply.

To improve the sanitary condition of Cairo, and convert

the Khalig into what it was originally intended for—namely, a pure stream instead of a foul ditch, many plans have been suggested, but all have proved abortive on account of the expense they entailed.

The following method of draining Cairo, proposed by Messrs. Cornish and Wallace, should meet every requirement, and in a very short space of time render the capital of Egypt one of the most healthy cities in the world.

To establish a complete system of drainage in Cairo it will be necessary to expend a sum of £480,750.

This system would include the establishment of a network of iron pipes, communicating with automatic watertight cess-pits, by means of which all fecal matter and refuse water would be aspirated from houses into four central reservoirs, to be thence propelled on to the waste land to the south of the city, where a sewage farm could be advantageously established. The cost of working this system would amount to £10,412 per annum.

In case Government should feel disposed to entrust this work to a company, the expense would be as follows:—

Cost of working	£
Interest on £367,700 (cost of network and machines at seven per cent.)	10,412
Sinking fund	25,739
	5,515
	41,666
Interest on £113,050 (cost of watertight cess-pits)	7,910
Sinking fund	1,713
	9,623

Grand total, £51,289.

There are said to be 54,000 houses in Cairo. A rate of £1 per house per annum would consequently suffice to pay for the removal of all filth, and provide for redemption of capital.

NOTE ON THE USE OF GALVANISM IN THE TREATMENT OF UTERINE DISEASES.

BY GEORGE ELDER, M.D.,

SURGEON TO THE SAMARITAN HOSPITAL FOR WOMEN, NOTTINGHAM.

At the present time, when medical attention is being directed to the electrolytic treatment of uterine myomata, more especially by the work and writings of Apostoli, it may be instructive to consider his method of application, and what he claims for it, and also what others are doing in the same direction, although not always on the same lines. I cannot do better than give, in Apostoli's own words, the manner in which his method differs from, and is superior to those hitherto practised.

In the *British Medical Journal*, of October 1st, Apostoli is reported to have said, at the annual meeting of the association, that "I have supplanted the old way of operating by a method which is—1. Precise, by the introduction of new galvanometers of intensity, exact counters and measurers of the electric current, etc. 2. Energetic, by an absolutely novel service of high intensity of current, which I have progressively carried according to the necessities of my cases, from 50 to 150 and 250 milliamperes. 3. Tolerable, in spite of the enormity of these doses, in consequence of the introduction of a new form of electrode, the wetted clay, which renders the cutaneous pole innocuous, and permits us to transmit through it, easily and without injury, a current of signal medical intensity. 4. Better localised, by a direct application of the active pole, by way of the vagina to the uterus, either in its cavity or in the substance of the fibroid deposit. 5. Thoroughly under control, by the exclusive choice of the unipolar method, etc. 6. More scientifically

exact, from the due appreciation of the topical effects of the two poles, and the precise chemical and anatomical indications peculiar to each of them."

Further on he says:—"The positive pole will be the remedy *par excellence* in cases of bleeding or hæmorrhagic fibromata," and "the negative pole will therefore be found to render invaluable benefit (though with the positive pole it is possible to arrive at the same point by a way more indirect and tedious), in those cases of fibroids accompanied by amenorrhœa and dysmenorrhœa, which are only too often the despair both of patients and medical men without such means at their command."

The battery used is after the Leclanche pattern, with large cells, and is of necessity a fixture. When by reason of atresia, or such an amount of uterine displacement as one often sees in conjunction with myomata, the sound cannot be introduced, then galvano-puncture is indicated; or when it is desired to shorten the treatment by combining it with intra-uterine applications. For galvano-puncture a steel trocar is used, which is passed into the most prominent part of the tumour, usually in Douglas' pouch, to the extent of one or two centimètres. For intra-uterine cauterisation Apostoli uses a straight platinum-sound, with insulated sheaths of various lengths, connecting this by means of a rheophore with the positive pole when the myoma is of the hæmorrhagic variety, and with the negative in all other cases, and always for making a galvano-puncture. During the five years Apostoli has been working at this subject, he has made 5201 applications of galvanism upon 403 private and dispensary patients, for a variety of gynecological ailments, with two deaths, although it is only fair to him to say that these deaths are attributed not to any fault in the method, but in one case to a mal-diagnosis, and in the other to intra-peritoneal mischief, originated by too deep a puncture. Included in the above number are 278 cases of "fibromata or hypertrophy of the uterus in some manifest degree," and of these Apostoli states that when his advice has been acted upon, permanent benefit has been obtained in ninety-five per cent. Broadly, he claims for his method the power of averting hæmorrhages, relieving neuralgic and pressure symptoms, in many cases arresting the growth of the tumour, and in some producing a marked diminution, with occasionally its disappearance, improving the general nutrition of the patient, with practically no danger to life or interference with the ordinary avocations. At the beginning of this year, Dr. Woodham Webb, of Paris, made known to us through the medium of the *British Medical Journal*, Apostoli's work, and myself and others journeyed to Paris to witness this new development of an old and hitherto unsatisfactory therapeutical agent. Every facility was afforded his critics by Apostoli, and so impressed were those who went, by the promise which the treatment offered, as well as by the honest, thorough manner in which his work was done, that many came away determined to give the method, in their own practice, a fair trial. The time is yet too short for those of us who are working at this subject to put before the profession authoritative testimony with regard to its value, partly because cases suitable do not occur every day, and partly because to get the full measure of benefit the treatment must be continued for a considerable period. So far as my experience goes, its efficacy has been proved in arresting hæmorrhage, in the relief of pain, and the improvement of the general health; but so far, I can only point to one case of uterine myoma where a decided diminution in size has

taken place; in this case the tumour had decreased quite one-third. I have seen enough of the treatment, and heard enough of it in the practice of others, to show me that its careless exhibition may be followed by most alarming consequences, and that if its value is to be properly tested, not only should something more than an elementary knowledge of medical electricity be acquired, but also familiarity with the diagnosis of uterine diseases, and the manipulations required in their treatment.

In the February and March numbers of the *American Journal of Obstetrics*, Cutter, of New York, gives the full text of fifty cases of uterine myomata, treated by galvanism, and in several material points his method differs from Apostoli's. He uses a Stoehrers' battery, capable of giving a direct current of twenty-seven ampères, and electrodes of the shape of an ordinary surgeon's director with the points and edges sharpened, attached to a long ebony handle. Unlike Apostoli, Cutter, in nearly all his cases, gives the patient an anæsthetic, and pushes *both* electrodes into the substance of the growth, usually penetrating the abdominal wall, unless the tumour is wholly pelvic, when vaginal or rectal punctures are used, carefully avoiding strongly pulsating vessels. The application lasts from three to fifteen minutes, the first being always short; and should symptoms indicative of profound shock supervene, the treatment is at once suspended. Several days' rest in bed is imperatively required after each operation. His results read as follows:—Cured, eleven; relieved, three; arrests, twenty-five; non-arrests, seven; fatal, four, or a mortality of eight per cent. It requires hardly to be pointed out how enormously this mode of applying galvanism differs from Apostoli's, and those only who are acquainted with abdominal surgery can appreciate the danger of thrusting electrodes through the abdominal wall into a myomatous growth. To my mind it is infinitely more hazardous than the performance of hysterectomy, and without the certainty, if successful of curing the patient. Objectionable as the abdominal puncture is, still more so is the rectal, where the conditions, according to our present notions of surgical fitness, spell disaster. To those interested in this department of uterine therapeutics, I commend a careful reading of the original papers, as a valuable lesson in how not to do it.

Up till now, surgery, whether by means of the major operation of extirpation of the growth, or removal of the appendages, has not had such a brilliant record as to justify us in neglecting any means which hold out the prospect of benefiting our patients without mutilation or risk, and no doubt the profession at large will be content to suspend their judgment upon this new departure, until a sufficiency of material has been accumulated upon which to base an impartial and authoritative opinion.

[December 18th.—Since the above was written, I have had in two more cases of uterine myoma evidence of considerable decrease in size, with satisfactory improvement in other respects.—G.E.]

A MONSTER FÆTUS.

By H. R. GREENE, M.D. (CAIRO).

THIS drawing accurately represents a monster born in Cairo on the 3rd of August, 1887. Dr. Freda, of the Sanitary Service, who delivered the woman, writes as follows:—

"The woman M. M——, Egyptian, aged thirty, of good

constitution, married, living in Fagallah, has had in all four confinements. The three first, in which she gave birth to two girls and a boy, presented nothing remarkable. In her fourth she brought forth a monster with two heads and

three arms. Labour lasted about two hours, the presentation being by the breech. The monster was a fully developed nine months' foetus, and was still-born. The mother is doing well."

OBSTRUCTION OF THE BOWELS.

By CHARLES BOYCE, M.D. EDIN.

THE great fatality accompanying obstruction of the bowels makes the condition assume to every practitioner great importance. The deaths set down under this heading in the Registrar General's Reports appear to be steadily increasing in number. In 1877, 1449 deaths were attributed to this cause; in 1880, 1610; and in 1885, 1919 deaths, of which 238 were produced by stricture of the intestines. Rational treatment depends on a sound pathology, and the classification suggested by Dr. Haven, in the *American Journal of Medical Sciences*, vol. lvi., is of such a simple and

complete nature as to recommend itself to clinicians. He arranged all cases under the following heads:—

1. Intermural, those implicating the intestinal walls.
2. Intramural, those caused by lodgment of foreign substances.
3. Extramural, those acting from without.

The two following cases both belong to the first division.

ANNULAR STRICTURE OF THE INTESTINE—OBSTRUCTION OF THE BOWELS FOR NINE WEEKS.

M. W—, aged fifty-four years, of lymphatic temperament, with a marked tendency to obesity, had never suffered from any serious ailment, no history of dysentery, and had never lived abroad. Mother died of cancer of liver. I was consulted on March 20th, on account of constipation which had lasted for many months; the bowels acted only at long intervals, and after taking aperients, there had been no action for four days before I saw her; she felt sick, and her abdomen was griped and distended. I administered an enema, but without much result, so I ordered an ounce of castor oil. On the following morning, as there had been no action, I again gave an enema, but again unsuccessfully; evidently there was total obstruction; no flatus had passed. I persisted in administering enemata twice daily till March 27th, when a large loose motion was passed. I now ordered cascara sagrada, with nux vomica, and the bowels acted regularly as long as I continued the former drug, but on leaving it off, great difficulty was experienced, and frequent resort had to be made to domestic remedies. This state of affairs went on till the 13th of May, when the bowels acted for the last time, after a dose of Epsom salts. Symptoms of chronic obstruction gradually supervened; the expression became anxious, the eyes sunken; the body lost fat, and became emaciated, and vomiting occurred from time to time; paroxysmal pain, with borborygmi and meteorism. The abdomen was considerably distended, with bulging at the sides; there was no tenderness except upon deep pressure in the left inguinal region, where an indistinct resistance was felt, which was assumed to be a fecal collection; vermicular action of the bowels was very apparent, especially towards the end, when the mere tap of the hand on the abdomen would cause great coils of intestine to stand up, distended with flatus, and exciting great pain. The vomiting was occasionally stercoraceous, and there was a constant feeling of sickness present, which prevented food being taken, with the exception of iced soda and milk; and indeed, even this had to be omitted owing to the pain it caused, and resort was made to nutritive enemata; whilst small quantities of champagne were allowed by the mouth. Flatus in small quantities was occasionally passed, but I may say that the nurse in constant attendance thought this was doubtful. The temperature remained normal till two days before death, when it registered 100°. The urine was secreted, but scantily, and was throughout very dark in colour. Rectal examination revealed nothing, and tubes used for giving enemata bent upon themselves or coiled up in the sigmoid flexure and rectum. Per vaginum, small indurated lumps could be felt in the anterior fornix, to a certain degree movable. The uterus was normal in length, as shown by the sound; there was no uterine discharge. She gradually sank, and died of exhaustion on July 16th, so that for sixty-three days there was no passage of feces—an unusually long period. From the 3rd to the 10th of June she was an in-patient of the West Kent Hospital.

During the progress of the case the operation of colotomy was frequently suggested to the patient, but always refused. Great relief was given on two occasions by introducing an aspirating needle into the prominent coils of intestine, and drawing off the pent-up flatus. No unfavourable result followed the procedure. At the necropsy the abdomen was greatly distended, and on opening it the large and small intestines were greatly dilated, and rolled out of the wound. On following the intestines a narrowing was found at the sigmoid flexure, which permitted only a probe to pass. The uterus was found to contain several fibromata, and these were evidently the lumps felt per vaginum. The other organs presented no appearances important to the case.

Here then we have a clinical history of considerable interest from many points of view. 1. Concerning the motions, standard authors generally draw attention to the flattened ribbon, or pipe-like appearance of the stools; but in the intermediate stage of this patient, between the two attacks of obstruction, copious-formed motions were passed; and this, as Curling, in his "Observations on Diseases of the Rectum," says, might be accounted for by the dilatation of the bowel below the stricture. Dr. Hilton Fagge, in the *Guy's Hospital Reports*, says: "I am for my part indisposed to place much reliance on the statement of a patient that the motions have for some weeks been abnormally narrow."

2. The quantity of urine, according to some writers, affords a means frequently of diagnosing the seat of the obstruction. Thus where it is low down, the quantity secreted is large; and scanty when high up; the diminished quantity in the latter case being due to persistent vomiting in part (Barlow); and in part to some reflex inhibitory influence exerted through the sympathetic nervous system upon the excreting function of the kidneys (Fagge). But here we have a stricture low down, where during the whole course of the obstruction, the quantity was greatly diminished. The same diminution I have also observed in another case of obstruction which lasted four weeks, where the cause was cancer of the upper part of the rectum.

3. The puncture of the intestines, and the withdrawal of flatus, afforded great relief on two occasions, and was not followed by any peritonitic symptoms.

4. The presence of fibromata in the uterus has an interest in connection with the diagnosis, such as the possibility of their pressure on the intestine being the cause of the obstruction.

6. This case also shows that the long rectal tube is not to be relied upon as an aid to diagnosis. Treves, in a recent lecture in the *Lancet*, says: "Enemata as a means of diagnosis are practically useless; still less useful is the long tube. This instrument is not only a delusion, but a snare, and its valuelessness as a diagnostic agent can be well demonstrated on the *post-mortem* table." In cases of fecal accumulation the long tube frequently proves of the greatest value, and is a rational remedy to adopt, but its use must be attended with certain precautions, such as having it well softened before using, introducing it slowly, dilating the bowel with the fluid at the same time, and examining the rectum with the finger from time to time to ascertain whether the tube has bent upon itself.

CANCEROUS STRICTURE OF RECTUM—OBSTRUCTION OF BOWELS FOR FOUR WEEKS.

Mrs. H—, æt. sixty-four; sister died of cancer; a delicate woman; suffered a few years ago from angina

pectoris; but her former illnesses had no connection with her present intestinal trouble, except an attack of diarrhoea which she had in July last. Bowels opened naturally for the last time on Oct. 10th. An enema was used on Oct. 17th, but could not be retained. After Oct. 24th difficulty was experienced in passing urine. Vomiting on one occasion was stercoraceous. On examination a rounded tumour was felt per vaginam and per rectum, occupying the pelvic cavity; it could not be felt above the pubes. She died on Nov. 7th. Twenty-eight days elapsed without her having passed fæces. A *post-mortem* was made a few hours after death, but permission was only given to examine the abdomen. A large schirrus mass was found in the rectum, totally obliterating its lumen, the bowel above being greatly dilated. At various points of the mesentery smaller nodules were found, one of which partially involved the small intestine.

In cases of chronic obstruction of the bowels the question of colotomy is one which must always be duly considered, holding forth as it does the prospect of prolonging life, or at least of alleviating suffering. My first case would have derived the full benefit of this conservative operation, and many years might have been added to her life had she submitted to the procedure; but in the second case we have an equally good example of our helplessness in dealing with cancerous strictures. In this particular case the small intestine must have become obstructed before long.

FROM GENERATION TO GENERATION: A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.,
F.R.S.L., ETC.

(Continued from page 549, December, 1887.)

AMONGST those nervous diseases, a predisposition to which is undoubtedly inherited, I shall instance, in the first place, *hysteria*. So important is this predisposition as a cause of hysteria that it is capable of developing not only a tendency or liability to it, but also the complete evolution of the disease itself; whilst the hysteria of parents or ancestors usually predisposes to hysteria in the children—thus denoting an inheritance of like tendencies, and especially in transmission from mother to daughter. Various other nervous affections, which have appeared in the ancestors, favour a disposition to hysteria in the descendants; just as it happens, on the other hand, that hysteria appears in one generation, and epilepsy, chorea, insanity in the next. Briquet has proved that more than a fourth of the female descendants of the hysterical suffer in their turn from hysteria; and Amann has recently stated that in 208 cases of hysteria he proved with certainty a hereditary tendency 165 times—that is in seventy-six per cent. All those phenomena which indicate the possession of a neuropathic predisposition have a decided influence upon the transmission of a tendency to hysteria: moreover, privation, insufficient nourishment, debility in the parents arising from senility; or chronic diseases, as phthisis, apparently favour the development of a tendency to hysteria in the children. The inherited tendency to hysteria may for a long time remain latent, until, in fact, some constitutional shock or epoch develops an outbreak of the disease. In other cases the transmitted predisposition may be strong and effective enough to develop it independently. It should, however, be remembered that in a few cases hysteria may result in a child from the mere fact of its imitating an hysterical parent.

That weakly constitutions manifest a greater predisposition, must be conceded, just as acquired conditions of debility favour the development of the disease. Herein is probably to be found the connecting link in those cases in which debility of the parent induces hysteria in the descendants.¹

Epilepsy.—The hereditariness of a predisposition to this affection is beyond all doubt, as is acknowledged by every authority who has written upon it. The predisposition itself may be transmitted directly from parent to child, or it may remain latent in a generation or two, and appear in the grandchild or great-grandchild; moreover, it may be traceable only in the collateral branches of the ancestry, as in hereditary maladies. Predisposition may also be connected with congenital formation, as is often evidenced in cases of chronic hydrocephalus, also in those in which there is a misshapen or unsymmetrical form of the head. Amongst other predisposing causes may be mentioned the scrofulous diathesis and idiosyncrasy; also the epochs of childhood and puberty, at which periods the nervous and muscular systems attain their maximum of sensibility and irritability, and the physical susceptibility is greatest. With regard to the influence of the scrofulous diathesis, Dr. Cheyne holds that epilepsy is as certain a manifestation of the strumous disposition as tubercular consumption, or psoas abscess; but it may be observed that the strumous diathesis, and a particular conformation of the head, are both very likely to descend from parents to their children.² In those cases of epilepsy which are hereditary, the affection is usually developed at an earlier age. In the great majority of cases epilepsy is developed between ten and twenty years of age, and especially at or about the period of puberty. According to Echeverria, the occurrence of the symptoms of hereditary epilepsy is before puberty; according to Reynolds, not later than the twentieth year. It may, therefore, be assumed that an individual with a hereditary predisposition, remaining healthy up to the twentieth year, will also escape epilepsy after that, so far as its development is excited by the hereditary tendency alone. Such individuals often suffer from eclampsia as early as during the first dentition, but afterwards again remain apparently healthy up to the outbreak of the epilepsy.³ Although the father or mother of the patient may never have had an attack, either of the grand-parents, or uncles or aunts may have been subject to it. Zacutus Lusitanus mentions the case of an epileptic man who had eight children and three grand-children afflicted by the disease. Stahl and Reininger adduce instances of the whole of the members of a family being attacked by it at the period of puberty. Boerhaave remarks that, like several other hereditary maladies, it often passes over alternate generations, and he adduces an instance in which all the children of an epileptic father died of it. Dr. Copland says: "I had, in 1820, a brother and sister some time under my care, who inherited the disease from their father, and they had two other brothers and one sister also subject to it—in all five. The fits appeared in all of them about the period of puberty, and one of the brothers died about the age of forty from apoplexy, complicated with the seizure. MM. Boucher and Casauvieilh state, that in 110 patients, respecting whom they had made inquiry, 31 were hereditary cases; and M. Esquirol found, that in 321 cases of epileptic insanity, 105 were descended from either epileptic or insane parents."

¹ Jolly.—Ziemssen, vol. xiv.

² Watson.

³ Nothnagel.

Amongst those cases in which the disease is produced by factors of a kind not appreciable anatomically, which at times affect the nervous system alone, at others the whole organism, inherited predisposition or tendency occupies the first place, and is of prime importance. Seeing that all observers are agreed upon this fact, I need not further cite either statistics or instances in its defence, although in addition to those already quoted, I may be permitted to mention the experience of Echeverria, who, out of 306 patients under his own care, had observed 80 with an hereditary tendency. With regard to this hereditary tendency to epilepsy, we must be careful not to limit it too much in its signification, as, for example, in assuming that epilepsy only and strictly in the forbears is calculated as strictly to reproduce epilepsy in the children. This view cannot be upheld for a moment, as owing to those phenomena of the law of variability which I have already referred to, and which are denominated metamorphoses in transmission (by which also the differentiation of individuals is necessitated and secured) it by no means follows that the ancestral or parental form of affection is strictly inherited by, or transmitted to the children, but that whilst similar in kind, it may be very different in degree. As Professor Nothnagel, of Jena, says: "The children of those parents may become epileptic who have been mentally diseased, but who have never suffered from convulsive affections. The fact is, hereditary disposition must be taken in a far broader sense, and the proposition may be enunciated that any neurosis in the parents, whether it be of a lighter or more serious kind, may plant in the children the germ which may develop into epilepsy. This obtains not only in regard to hysteria, hypochondria, and catalepsy, but I have observed cases where—e.g., the mother suffered for many years from pronounced migraine, and with this exception there was absolutely nothing else in the way of family tendency to be found, and yet a daughter was hysterical, and a son epileptic. From my experience, I am even inclined to ascribe to neuralgia of many years' standing in the parents, a capacity of producing epilepsy in the children. There are even not wanting instances where, in connection with a mere 'nervousness' of the ancestors, epilepsy made its appearance in the descendants."

I have already stated that in hereditary epilepsy the first occurrence of its symptoms is, according to Reynolds, not later than the twentieth year; and to this I may now add that an individual who has inherited a predisposition to epilepsy may escape its development altogether if his general health remains satisfactory up to this period. This latter statement depends, of course, upon the assumption that the attack is produced entirely as the result of the inherited predisposition, and does not affect the occurrence of epileptic seizures from other causes. Although epilepsy may be caused by many factors, such as alcoholic and sexual excesses, prolonged mental strain, disturbances of nutrition, as produced by defective nourishment, etc.; external injuries, etc., yet none of these are so effective in exciting "the central epileptic change" as hereditary predisposition. Why this inherited tendency should be so much more active during youth—from the seventh to the seventeenth year—we really cannot satisfactorily explain, notwithstanding the many theories which have been propounded to account for it: we can only at present accept the fact, and trust that time may throw some further light upon this interesting question in the future. With regard to prognosis, Reynolds maintains that those cases are least amenable to treatment in

which the source of the disease is involved in the greatest obscurity.

Chorea.—As in hysteria, epilepsy, etc., there is a marked hereditary predisposition to chorea—i.e., "an hereditary transmission of a special susceptibility to irritation—an impressionability of the nervous system"—generally associated with constitutional debility. Thus, as quoted by Von Ziemssen:—Dr. Huntington, of Long Island, with his father and grandfather (also physicians) says he has observed entire families of choreic persons, in which the disease was propagated until once a generation had been overleapt, when the hereditary disposition in that family ceased. In these cases the chorea began between the twentieth and fortieth year of life; attacked men and women alike, and usually led to mental disease, often associated with suicidal tendencies, and finally to death. That chorea may be congenital—i.e., transmitted hereditarily, admits of no doubt, although the occasions of such actual transmission may be regarded as comparatively rare. Fox has recorded a case in which the child, a male, was born six weeks before the period, and from the first hours of his life he suffered from violent choreic movements, which gradually developed into epilepsy in his third year; after which he had no further attacks, but his speaking and walking were defective up to his thirteenth year. Richter also mentions chorea as occurring congenitally in the case of two girls whose mothers had been frightened when far advanced in pregnancy. From their birth the children suffered with chronic spasms, which ceased during sleep, and eventually disappeared almost entirely.

That chorea is often mimetically contagious, is also a well-established fact: thus Leube saw two girls, of the ages of sixteen and seventeen, hysterically predisposed, who acquired chorea in consequence of intercourse with another girl, aged twelve, who had the disease. Bricheteau also mentions the following interesting case:—A girl was admitted into a ward in the Hôpital Necker where there were girls who were hysterical, and who had formerly been the subjects of chorea, and within six days eight other patients in the same ward were taken with chorea. The further spread of the disease was arrested by isolating the chorea patients. The intensity of the symptoms varied greatly; some of the attacks lasted for months. In connection with such contagious or imitative cases, the especial point to remember is that a *distinct predisposition* seems to be necessary to propagate the disease by imitation: otherwise the number of instances would be much greater than it is.¹

In this connection I may now briefly refer to *alcoholism*; the pernicious effects of alcoholic excesses on the nervous system being well known, and these are, according to all competent observers, markedly hereditary in many cases. In cases of inherited predisposition to chronic habitual drinking, it is not absolutely necessary that the parents or ancestors should have been drunkards, but that the family is characterised by that form of unstable nervous organisation which I have already alluded to as a neuropathic predisposition, and that the neurotic taint which manifests itself in other members in such affections as hysteria, epilepsy, and insanity, will be manifested in these cases by an intense, if not insuperable, craving for alcohol. At the same time it should be borne in mind that owing to the tendency which acquired predispositions have to reproduce themselves in the offspring, drunken parents may actually transmit this predisposition to their children, or if not, then

¹ Von Ziemssen.

such a state of disordered cerebral nutrition as may express itself in epilepsy, insanity, idiocy, hysteria, weakened will-power, or mental instability. Here again we see how the differentiation of individuals is maintained by pathological processes; for, given a drunken parent or parents, their children will assuredly inherit such a neuropathic disposition, as in the case of one of them may manifest itself in idiocy, in another as epilepsy or hysteria, in another in weakness of will, and in yet another or others in uncontrollable alcoholic craving; some may escape in their own persons, but only to hand down the heritage of their parents' shame to others and succeeding generations. Dr. Richardson has well said:—"The solemnest fact of all bearing upon the physical deteriorations, and upon the mental aberrations produced by alcohol, is that the mischief inflicted by it on man through his own act and deed cannot fail to be transmitted to those who descend from him, and who are thus irresponsibly afflicted. Amongst the many inscrutable designs of nature, none is more manifest than this, that physical vice, like physical feature and physical virtue, descends in line. But not one of the transmitted wrongs, physical or mental, is more certainly passed on to those yet unborn than the wrongs which are inflicted by alcohol. Many specific diseases engendered by it in the parent are too often stamped in the child; while the propensity to its use descends also, making the evil interest compound in its terrible totality." It is unnecessary for me to dilate upon the many acute and chronic diseases caused directly and indirectly by alcohol; but the point on which I would especially insist is that the protean pernicious effects of alcohol taken in excess do not, unfortunately, end with the miserable life of the poor drunkard, but are passed on to his irresponsible children as a legacy from violated nature—an indelible brand, an inherited curse—which may express itself in a distinct neuropathic predisposition capable of developing insanity, hysteria, epilepsy, impaired volition or mental instability, and of reproducing the primary vice in which it has originated. Of the real nature of this predisposition we know nothing, beyond the probability that the nervous centres are somehow implicated in its production, but we must for the present be content to accept facts as we find them, and trust that future researches may be able to throw light upon a subject which is now obscure and mysterious.

Having now considered the hereditary element in insanity, hysteria and its allies, epilepsy, chorea, and alcoholism, I might readily refer also in detail to neuralgia, cephalgia, migraine, tubercular meningitis, sanguineous apoplexy, locomotor ataxy, progressive muscular atrophy (Cruveilhiers' paralysis), pseudo-hypertrophic muscular paralysis (Duchenne's paralysis), sclerosis, and other nervous diseases which are alike subject to heredity, but I think I have adduced sufficient evidence to support the principle for which I am contending—viz., that whether the nervous system contains the *fons et origo* of heredity or not, its diseases are markedly hereditary; furthermore that the pathological differentiation of individuals is manifested to an extraordinary degree by the transmission of nervous diseases, for, given a neuropathic predisposition in the parents, it is found capable of developing a tendency in the offspring not only to itself but also to hysteria, epilepsy, chorea, insanity, neuralgia, and in fact to ring the changes on every known variety of nervous disorder or disease. Thus we see in every family, the members of which have inherited a neuropathic predisposition, that it may not only develop into various forms of

nervous disease, but that each member has inherited *something* which the others have not, whilst some may only act as mediums for transmitting the predisposition to a future generation, and at the same time they themselves may show no evidence of its possession. The differentiation of individuals is absolutely necessitated physiologically and psychologically by the interaction of heredity with the law of variability, and so it must be pathologically for the reason I have elsewhere stated—viz., all morbid action is but a modification or perversion of some natural or normal action or function; and all the physical results constituting morbid structural alterations are mere perversions or modifications of natural or normal textures, or, at most, analogous textures fabricated from the same materials by like processes. Every living individual, therefore, differing as he does from every other physiologically and psychologically, must also differ from every other in his pathological tendencies; and I believe that ignorance of this fact is the most fruitful source of false views both in pathology and practice. As too much stress cannot be put upon my argument in this direction, I once more briefly summarise it here. By the law of heredity, all living beings tend to reproduce themselves in their offspring physically, mentally, and morbidly; but owing to the law of variability which interacts with that of heredity in the case of every individual, the likeness is never perfect—the ideal law of heredity that like produces like is never attainable. We see this even in the case of twins, whose resemblance to each other, however striking, is still far from perfect. However much a child may resemble its parents—or one child another—essential differences will be found externally and internally, physically and mentally, and with regard to their pathological tendencies. As in health so also in disease: Nature preserves the type by varying the individual; and as in health so also in disease, the individuality of every living man is necessitated and maintained by the law of variability. The phenomena of variability in health are seen in the physical and mental differentiation of every individual from every other, however closely allied; the phenomena of variability in disease are seen in the differences of individual constitutions, as to their mode of manifesting the effect of the same morbid cause, and their relative power to sustain it, and in the metamorphoses or transformation in transmission, to which I have recently alluded. The great principle for which I am contending is the due recognition of individuality in every case presented to us, remembering always that physical and mental differentiation necessitates the differentiation of pathological processes; and that co-operating with the great law of heredity which tends to produce like from like is the equally potent, if subservient, law of variability, which necessitates our differentiation from each other physiologically, psychologically, and pathologically, and by means of which our individuality is developed and maintained.

(To be continued.)

CONSULTANT TYPES—GOOD AND BAD.

By "ARMIGER."

(Continued from page 554, December, 1887.)

TAKEN altogether, my experience has shown a marked difference in the comparative type of town and country consultant. In the latter case the position has been too often the result of mere chance, of accident, perhaps of

the desire to be the medical magnate of the district, a desire favoured by circumstances, and less the result of any real ability, for the general type not to be affected. In the case of any man who proposes to be a consultant in London, or any large city, the mere facts of wealth, connections, or influence, will not avail much; there must be genuine ability, actual superior knowledge and experience, or opportunity for experience. Moreover, his ability must be recognized by his professional brethren. In the country this is different; a man may be the leading consultant, hold the best position and have the best patients, and yet be devoid almost entirely of ability. Time is changing this to a great extent, but it is sufficiently the case to be looked upon as the rule. But where the difference is most marked is in the display of amenities. So far as my observation has gone, the country consultant compares unfavourably with his town *confrère* on the points of courtesy and fair dealing. Not but what there are many of the worst type to be found among town consultants, men who, if they get a chance, will entice the patient away altogether. They abound, unfortunately. Nothing is more common, when a person living in the country goes up to town, than to consult some of the town men, especially if there is any pet ailment, real or fancied, without informing the usual medical attendant. This has happened to me many a time, and I have been surprised at the courteous intimation of the fact I have received subsequently. Under the circumstances this was quite uncalled for, no rule of professional etiquette having been infringed, and any notification of the fact to the usual attendant a purely voluntary matter. Yet scores of times I have had letters from London men to say that they had been consulted by some of my patients. While, of course, such an action might be pronounced as only good policy, still one cannot help feeling that it is both honourable and gentlemanly.

As a rule I have found the greater the man the greater the courtesy. Sometimes, however, it has been the other way. Not long ago a patient went to London by my advice for treatment, circumstances at his home being unfavourable. The case was not by any means of an obscure or doubtful character; yet the physician under whose care he went as a paying hospital patient traversed most pointedly all my decisions and diagnosis in his statements to relatives, and would not even write to me until openly taxed with duplicity, when he made a lame attempt to disclaim any doubt as to the correctness of my diagnosis. The object in this case was to persuade this patient to enter his "*private hospital*." Dr. F— was of this type—undoubtedly a good man professionally; but with a very marked moral obliquity. He had one of these private hospitals (nothing more, really, than a good lodging-house), and whenever he had a patient from the country, he left no stone unturned to get them to enter his hospital. It paid him well. An enhanced fee for any operation, heavy charges for boarding, nursing, and attendance, and for his visits, made every patient valuable to him. The lodging-house keeper, called the lady superintendent, was merely a salaried servant, and the nurses and ordinary attendants were the same. All the boarding was superintended and purveyed by himself; in fact, he was the real lodging-house keeper, and pocketed all the profits. Professional dignity had no real meaning for such a man. There are, unfortunately, many men of such a type in London, and one or two of our large towns, who carry on this sort of traffic. It cannot surely be difficult to see how such a state

of things may warp a man's ideas. One effect produced is the marked tendency to look for any approach to their own particular speciality. If it is found to be present at all, or any excuse for saying it is present can be made, the patient is by hook or by crook persuaded to enter the *hospital*; and as there is little or nothing to cure, the patient is discharged as a brilliant case. There is, unfortunately, too much reason to believe that in many cases patients have been told that certain diseases were present which had no existence. Weak-minded, susceptible people have been easily persuaded that they had certain special affections requiring special treatment. One case only may be mentioned, where a lady suffering from emphysema was induced to submit to a course of *private hospital* treatment for uterine mischief which never had any existence. This wilful deception of patients recalls to my recollection two gentlemen practising as surgeons. The first was remarkable from great affectation in style of dress. Allowing his hair to grow long, with a bushy beard, dressing always in black, shewing an immense expanse of shirt front with prominent jewelled studs, he certainly cut a figure, which did not appeal to good taste. Loud in speech, strongly self-asserting in manner, possessed of great shrewdness and undoubtedly great professional knowledge and skill, he acquired an extraordinary ascendancy over patients. He did this by lecturing them; no matter what ailment presented itself, it was enlarged upon. Every professional term which could be brought to bear was introduced, and generally he succeeded in overwhelming the patient with such a periphrastic torrent that they were convinced he was the most erudite and able man of the day. He simply bamboozled his patients, prostituting great ability and operative skill to the most patent charlatanism. By pronouncing many benign tumours and simple ulcers as malignant, he claimed credit for having cured cancers without number. Bladder affections all with him depended on the presence of a stone, and proceeding to cure the simple ailments, he claimed to have removed the stone without operation. Ordinary uterine affections were all due to misplacement, and introducing a pessary for a time, while the simple ailment was treated, claimed credit for having cured the graver affection. A good example of his style of working is furnished by the cure of a hysterical woman, who suffered from the ordinary "*globus*." He at once assured the patient that the case was most serious, and that she had *only come to him in time*. Examining the throat in a fussy way, and introducing his finger, he asked if she was in the habit of carrying articles in her mouth. The reply was, "No." "Don't you sometimes put pins in your mouth?" "Well, I might do so." "That's it, I feel sure of it; you've swallowed one—I can feel it. I thought it must be something metallic; if it be not removed it will cause your death ultimately." He examines again. "Ah! now I can feel it distinctly; it lies below the cricoid cartilage, and is involved in the aryteno epiglottidean fold; the point is directed towards the superior anterior angle of the sub-tracheal tissue, and the head is pressing on the lateral branch of the recurrent nerve. Now, keep quiet just a moment, and try to bear what I am about to do. I will be as gentle as possible." He then introduced a pair of throat forceps, and rummaging about in the larynx for a few seconds, withdrew the forceps, holding a pin which he had conveyed between the blades by sleight of hand. This astonished the patient, whom he informed that the damage done was very great, and that it would give

rise to symptoms for some time. He thus prepared the way for recurrence of the "globus" sensation and a long course of subsequent treatment.

This woman had unbounded faith in this individual, and submitted to all his exactions with readiness for a time. He acquired a wide reputation, and actually worked into a good consulting practice, to the chagrin and dislike of his professional brethren, who could not refuse to meet him, although they unavailingly denounced him as a quack. It must be said that he never acted badly towards his medical *confrères*, but was usually fair and conciliatory, although he could not help indulging in rhodomontade.

Mr. H—, the second example of this bombastic type, was a man of inferior social extraction, and having been unable from this cause to obtain a good education in early life, when circumstances improved and enabled him to avail himself of every opportunity of obtaining it, failed somehow to acquire that outward indication of being a well-educated man which is usually seen. Perhaps his early life and social surroundings may have acted to prevent this, but certain it is that in almost everything the impression conveyed was want of refinement. Choosing the medical profession, possessed of marked intelligence and great zeal (he was of Jewish origin), he also possessed unbounded ambition. He passed well, obtained good appointments, and after a term as house-surgeon to a leading provincial hospital, settled in the same city. Combining shrewdness with unscrupulosity and good professional knowledge, he continued by a system of sheer humbug to obtain a wide practice. Pursuing exactly the same tactics as Mr. G—, he obtained the unbounded confidence of a certain sort of people. Unfortunately, his want of refinement and *savoir faire* led him to be aggressive, and in many instances unprofessional in conduct. In consultation he was overbearing, and would by some means or other convey to the patient and friends the knowledge that he differed with the usual medical attendant. This has had its inevitable effect, as no man who aims at a consultant's practice can afford to make himself unpopular and feared or disliked by his professional brethren. I learnt a short time ago that the prosperity had not continued, and that a declining *clientele* has been experienced.

THE MEDICAL MAN OF THE FUTURE.

BY ALFRED H. CRESPI, WIMBORNE,

LATE EDITOR OF THE "SANITARY REVIEW."

THE recent election to an Assistant-Physicianship, at Guy's Hospital' of Dr. E. C. Perry (late Captain of Éton, Fellow of King's College, Cambridge, and Senior Classic in 1880), following by a short interval that of Dr. Donald Macalister (Senior Wrangler and First Smith's Prizeman in 1877, and Fellow of St. John's College) to a Physicianship at Addenbrooke's Hospital, Cambridge, furnishes matter for serious reflection. No one acquainted with medical questions can be ignorant that Cambridge is now pouring into the medical profession nearly fifty medical graduates a year, many of them first-class men; while Oxford, which has just resuscitated her ancient medical school, is sending in a smaller, but I believe an increasing stream of highly-trained graduates. Trinity College, Dublin, long a brilliant medical school, is also adding largely to the supply of well-trained practitioners; while the remaining British Universities are literally pouring in their large contributions, and engaged in the same work is

the College of Surgeons of England, which adds a contingent of, it may be, thirty or more Fellows by examination every year. This is going on simultaneously with the enormous strides taking place in the education of the Licentiates of the Royal Colleges of London, and the greater stringency of the examinations at all, even the humblest and remotest training body. Dr. Banks, the President of the British Medical Association, stated in Dublin recently that the medical profession had sometimes been disparaged because so few comparatively of its members were graduates in Arts, and so were at a distinct disadvantage in comparison with the sister professions of the Church and the Law, in which, he added, a degree in Arts was the rule. Although Dr. Banks informs me he meant his remarks to apply to Ireland, it will be news to most people that solicitors are commonly graduates in Arts. Indeed, it might be maintained that M.A.'s are as scarce among them as Wranglers and Classics in the medical profession; and it will, no doubt, reassure the public that the complaints as to the inferior quality of a moiety of the candidates for Holy Orders are, on the authority of the Physician to the Queen in Ireland, ill-founded. Even at the Bar, however, the proportion of non-University men is large, and the army almost necessarily receives a very meagre sprinkling of graduates. The fact remains that the portals of the medical profession are being guarded almost more jealously than those of any other profession. The clever chemist cannot find admission to it by passing a simple examination. No surgeon's assistant can, after four or five years' routine discharge of his duties, get a diploma by the grace of any medical corporation. No medical bishop can confer admission on any *protégé*. In short, nothing remotely resembling a typical theological college, with its two years' course and three or four tutors, exists in medicine; nothing like the slipshod work of a country attorney's articulated pupil; nothing like the examination required of militia lieutenants seeking to join the regular army, or the lenient examinations of certain of the Bishops—the more lenient the more inferior the quality of the candidate, and the fewer his educational advantages—remains in the medical profession. After passing a more or less severe examination, or taking a degree in Arts, every medical student has four, five, or even six years' careful and systematic training in a well-appointed medical school, and every few months his career is marked by a searching examination lasting several days, and at which half the candidates—sometimes far more, seldom fewer—are stopped and referred to their studies, and often the curriculum is materially lengthened in consequence. In another ten or fifteen years it may be, that should the present progress continue, a quarter or a third of the medical practitioners of the United Kingdom will be graduates in Arts, and from two-thirds to three-quarters will hold University degrees in Medicine.

All this is as it should be. But it must not be forgotten that with inferior men getting rarer every year the mere possession of an ordinary M.B., B.A., will not obtain for the holder a position on the medical honorary staff of a large hospital; and the M.R.C.S. has long ceased to be any passport to the surgical side. On the staff of one of our provincial schools there were, fifteen years ago, only four members of our ancient universities; there are now sixteen, some of them first-class honourmen. It may be that the days are nearly come when there will be a repetition of the state of things which Bacon described when he said that the lawyers had the most money, the clergy

the highest honour, but the physicians the greatest learning. The time may soon return when the London and Dublin Colleges of Physicians will again demand a degree in Arts from Oxford, Cambridge, or Dublin, of all candidates for their Fellowship. Anything that tends to fill the country with well-read, highly-trained practitioners is to be commended. Unfortunately there is another side to the picture, and to this I propose directing attention. No profession is so exposed to the depredations and encroachments of unqualified pretenders, and the chemists and the quacks, though I do not mean to put the two together, will hardly fail to profit largely by the present state of affairs. Again, the multiplication and ever-growing abuse of hospitals and dispensaries are curtailing the slender incomes of medical practitioners. Perhaps the only possible occasion on which small shop-keepers and skilled mechanics can consult Fellows of Trinity College, Cambridge, Fellows of the Royal Society, Senior Wranglers and Senior Classics is in a hospital, and they are not slow to use the chance. Nor must the rapidly-diminishing death-rate and the decreasing sick-list be omitted as most important factors in cutting down the demand for medical services, and that, too, even to a greater degree than the increase of population provides more patients. The sale of patent medicines is also becoming larger and reaching farther, while the frequency with which well-to-do people cut out and use prescriptions from the *Family Doctor*, and other similar publications, can only be duly appreciated by the medical man who finds that his friends and neighbours dispense with his services as much as possible, and often contrive, and not unskilfully either, to treat even serious complaints. The work of sanitary associations and of the St. John Ambulance Association all tends in the same direction—teaching people how to do without the doctor except in cases of urgency. A thousand well-educated medical men set up every year in the United Kingdom. The facilities for turning out a large body of very superior practitioners are being greatly developed everywhere, and though the percentage of great intellects may not be larger than formerly, far more is made of the rank and file than was possible or indeed attempted twenty years ago.

Medicine is not a popular calling with the rich and great, and it has peculiar disadvantages. The young doctor, settling in a fresh place, too often finds himself less respected than he deserves. He has none of the leisure of the retired officer; none of the opportunities for social intercourse, dinner parties, and out-door games of the clergy. As for long holidays entailing absence from home of six months, nine months, fourteen months, and so forth, as are not absolutely unknown on some pretext or another among the well-to-do local rectors, he cannot indulge in them. He must be prepared to find that some inferior theological student, admitted to Holy Orders by the too-lenient grace of an over-kind bishop, will possibly be thought a better scholar than himself, though he may have taken a good degree in Arts and passed six years in medical studies. But there are even worse drawbacks. The practice of medicine is exhausting, responsible, and arduous to a degree. With the rapidly-increasing numbers of Old University men a large percentage of young doctors have to begin as assistants, while they look around for openings, or in country places as club and parish doctors. Can contrast be more painful than between the refectories of Christ Church and Trinity, with their graceful and refined tone of thought and their animated conversation, and the lonely surgery of a country parish doctor, where he is to be found

three times a day (Sundays not always excepted), handing pieces of plaster or boxes of pills to ignorant peasants or stolid colliery labourers?

What other profession can present such a discipline of self-sacrifice as is the lot of the man whose thoughts are filled with the subtle reasonings of Kant and Spinoza, the speculations of Max Müller, and the sweet periods of Spenser, before whom float visions of the gorgeous colouring of Raphael, Francia, and Michael Angelo, who can in a waking dream feast his eyes on the splendid canvases of Dante Gabriele Rossetti, and Burne Jones, who finds delight in the masterpieces of ancient sculpture and mediæval architecture, and then has to come down, for it is a sad crushing coming down, to the level of a Cardiff dock-yard labourer, or to ministering to the imaginary ailments of a Birmingham tradesman's wife. Sometimes the crushing labours of the highly cultured and learned medical man seem sadly misplaced, and it might look as if far inferior men, men whose training had been rigidly confined to the subjects barely sufficient to force an entrance through the jealous portals of the College of Surgeons, would be quite good enough for the work to be done; and yet it may be that the isolation of the country doctor's life, the disintegration of professional jealousies and competition, hardly dreamt of in the Church and other more favoured callings, and which make firm friendships among local practitioners rare and precarious, render it all the more important that he should be a man of the highest culture and acquirements, not because of its earthly rewards and recognitions, not because he is necessarily enabled to do more good to his suffering and little-appreciating neighbours, but because it unites him to the good and great of other lands and times. The unutterable weariness and monotony of a country doctor's life would at times be too crushing to be endured could he not turn to other topics and other thoughts. The great thoughts of the past, the glorious achievements of art and science, the measureless promises of the future he can grasp and rejoice in, and though necessarily lonely and with fewer opportunities than most of his neighbours of having social intercourse and foreign travel, he can pass his life contentedly if not happily, respected if not highly honoured.

The world is moving, and the outlines of physiology are becoming in many cases a part of the education of most people; at any rate, there is not that dislike of quasi-medical topics that obtained thirty, or even twenty years ago, so that a doctor who is only a doctor, however well-trained, is more likely to be appreciated for his attainments. At the same time, so removed are medical studies from the path in life of most educated people, that perhaps no other body of professional men would gain so much by culture, a wide range of general reading, and some proficiency in studies of common interest. The world can more easily judge of mathematics, classics, modern languages, letters, and popular science, than of mere skill as a physician and surgeon. Would that I could truthfully add that Medicine offered at least one reward, an assured and modest competence. That, alas, is not so. Squeezing shillings and half-crowns out of poor peasants, and receiving the bitterly-begrudged and hard-earned pittance of the colliery club or parish appointment are not calculated to improve one's self-respect, and yet they sum up the life of too many doctors, and of some, too, who have had a public school and real University training—meagre pittances that a small tradesman would despise, salaries only equal to those of a second-rate mechanic, incomes that in too many cases fall

far short of the earnings which the doctor is commonly supposed to get, and not more than sufficient to meet half or a third of his current expenses. Medicine is rarely a calling in which a poor man can prosper, and not often one to attract the rich man of good birth; and yet, in spite of all this, it is not to be regretted that year by year a higher and more perfectly educated class is taking to practise, and that ten years hence most large villages may have among their local doctors—men equally at home in the past and the present, men whose knowledge of Dante and Shakespeare, whose familiarity with the higher mathematics and the most recent speculations of science, and whose proficiency in their own calling will make them worthy to be members of that ancient and glorious profession on which Wren and Locke, Acland and Rolleston, Paget, Jenner, and Oliver Wendell Holmes, and last, but not least, Livingstone and Carpenter have shed imperishable lustre.

VICTORIA INFIRMARY OF GLASGOW.

BY ALEX. W. WALLACE, M.D.

SCOTCHMEN call an endowed school for the free education of boys or girls a *hospital*, and a house for the sick an *infirmary*, at least, so it was before railways and telegraphs. Farther, having found out that these prisons for the young were more of a curse than a blessing, they employed a large amount of the funds of George Heriot's Hospital in founding day schools, and pulled down Watson's Hospital altogether, building the Royal Edinburgh Infirmary on the site. They have so far conformed to southern nomenclature as to have "hospitals" for sick children in both the capitals; but *infirmary* still holds its ground as the designation for hospital for adults.

The Victoria Infirmary of Glasgow is, however, as yet only a potentiality. It exists in the mind of the architect; it exists also, potentially, in certain sums, in some part in one of the city banks, but in considerably greater part in the pockets of the good people of Glasgow. It exists, too, in the necessities of many hundreds of sick people in the back streets and lanes of that great city.

Glasgow may be considered as the biggest workshop in the world. One hundred years ago its population was about sixty thousand; now, including its suburbs, it reaches about three quarters of a million. The reason of this rapid growth is that it has combined the industries of three great English cities. It has the coal and iron of Birmingham, the cotton of Manchester, and the seaport advantages of Liverpool. One hundred years ago the Royal Infirmary was founded. As the city grew the Infirmary grew also, till it had reached 500 beds. Fourteen years ago the Western Infirmary was built in order to provide clinical teaching in connection with the University Medical School, which had been removed to the West End: it provides about 400 beds. The two great Infirmaries, together with some other small hospitals, only provide a bed for about every 700 of the population. It is a result of the great amount of manufacture going on in Glasgow that considerably more than half the families it contains occupy but one or two rooms each. In fact, 420,000 people are housed in 88,000 one- or two-roomed dwellings—the single rooms composing little less than half the entire number. It will be at once seen how inadequate the hospital accommodation is for such a population, even if they could call all the 1,000 beds their own. As a result

of this the existing hospitals have to refuse necessitous cases in great numbers, except at the very healthiest period of the year. It is almost ten years since Dr. Eben Duncan brought before the Southern Medical Society of Glasgow the need that existed for a new hospital for that portion of the city which lies to the south of the Clyde, and which contains a population of about 240,000, chiefly artisans and working-men. The story of the ensuing "ten years' conflict" with its difficulties and discouragements is exceedingly interesting, but we have not space to give it here. Suffice it to say that the promoters of the hospital are within sight of an Act of Incorporation; have secured a splendid site on a rising ground, where the Infirmary never can be built in, and that in spring they expect to "arise and build."

The Infirmary is to be on the pavilion principle. At present only half the building for the administrative department and one pavilion are to be erected. There will be accommodation for about sixty free patients in the pavilion, and about a dozen paying patients in temporary wards in the unused part of the administrative buildings. The undertaking seems to us to be of great promise. It has originated in the Southern Medical Society, and as it has thus received the hearty interest and co-operation of the medical men of the district, we expect that many mistakes which have occurred in connection with other hospitals will be avoided here. We sincerely hope that the "subscribers' lines," which are in use at the other Glasgow hospitals, will have no place in the Victoria. The "selection of the fittest" ought to be the object kept in view, and this can best be attained through the medical men practising in the district, aided by the missionaries, district visitors, and other benevolent agencies at work among the people.

We believe that the working classes could do far more in providing for their hospital and dispensary relief than is commonly imagined. The South Side of Glasgow is far behind the West End in the possession of wealthy residents, yet we find that the congregations belonging to two undendowed denominations on the South Side raise about forty-five thousand pounds a year for religious and benevolent purposes. This is effected by a very complete organization of voluntary collectors. The Infirmary directors ought to originate a similar organization throughout all the workshops, making a collection monthly or quarterly, and if the work is properly gone about the revenue of the Infirmary will be just as secure as if paid out of the Consolidated Fund. If this is done there will be three hospitals in Glasgow whose financial condition will make the mouths of treasurers of London hospitals to water. The "Royal" has been able during the century of its existence to accumulate a capital of some £115,000; and the "Western," during the brief period of its existence, has been able to save £48,000. There is just one hint we would like to give the directors: they are canny Scotchmen and will know how to use it. Stimulants form a very heavy item in the expense of many hospitals, yet there is no evidence that the patients are anything the better for them in such large quantities. It is just the whim of some physicians; but if you let in a stimulating doctor you cannot interfere with him, so *don't let him in*.

MONTHLY REPORT ON NEW PREPARATIONS, FOODS, DRUGS, INVENTIONS, ETC.

Carnrick's Soluble Food (Milk Wheat Food).—Doubtless the idea that because flesh is the food that is

nearest in structure to the flesh of the human body, therefore it must be the most easily assimilated, has had a powerful influence in giving rise to the belief that flesh meat is the most nourishing and sustaining food which can be used; very widespread is this belief, both inside and outside the profession, yet what foundation has it, either in observation, experience, or common sense? Our bodies are not built up of nutriment as a wall is built of bricks. So far is this from being the case, that even the fat of the food is often deeply altered in its chemical constitution before forming part of the body.¹ Much more is this true of muscle. There is no more sense in giving flesh meat by preference to an emaciated man than there would be in feeding a chlorotic girl on blood puddings. Observation teaches us that as a rule flesh meat by no means readily yields itself either to primary or secondary digestion. A weak stomach rebels against the full meal of butcher's meat, and the damaged liver is not behind in its protest, and converts the meat peptone into uric acid. Yet in spite of these warnings, medical men have been trying to make flesh more digestible by some mechanical or chemical process. Beef tea and chicken broth were the earliest inventions. Very digestible they were found to be, for the very good reason that they contained almost nothing to digest. Next to them are the pounded up beef teas, in which by dint of pounding and stewing, the muscle has been reduced to an impalpable powder, and is diffused through the fluid. Doubtless a large amount of solid proteine matter finds its way into the stomach, but in how far the individual particles retain their solubility in the gastric juice does not appear. As far as we recollect, Sir W. Roberts made no experiments on the solubility of beef tea grounds by pepsine. The latest improvement has been pre-digesting the meat with a digestive ferment. This is no doubt the only scientific method of procedure, but the resulting product is anything but palatable, and is nowise fitted by the process it has gone through for assimilation by the liver. In our opinion peptonised meat should be kept for rectal alimentation. It is now a good many years since milk began to make its way as a food for the sick, and those suffering from imperfect digestion. It stands to reason that a substance which is specially prepared for assimilation by the stomach, should be digested more easily than anything else—and such has proved to be the case. But there are cases in which the curd which is formed when it passes into the stomach is incapable of digestion. This occurs both in infants, invalids, and aged people. The Maltine Manufacturing Company have submitted to us a preparation which overcomes this difficulty. In it milk is peptonised, and is mixed with malted wheat in such proportion as to imitate very exactly the proportions of casein, sugar, and fat in human milk. The mixture is dried, and is reduced to a fine powder. It is only necessary to mix it with water, and boil it for a short time, to have a most digestible liquid food, suitable either for infants or invalids. The casein having been acted on by a digestive ferment does not form curd in the stomach. We have tried it, and in point of taste it is the only unobjectionable form of peptonised food we have met with. We are perhaps fastidious, but we never could get through a basin of milk peptonised in the usual way; it was decidedly—well, not nice. Of the digestibility of the Maltine Company's soluble milk food there can be no question.

¹ *Foster's Physiology*, 4th ed., p. 428.

Houdé's Pastils of the chlorhydrate of cocaine have been some time in the hands of the profession, and they have been freely used and tested by some of the best specialists and general practitioners. Experience has pronounced in their favour, especially in affections of the larynx and air passages. The advantages they possess are manifold. They are manufactured with care as to dosage, each pastil contains two milligrammes of the chlorhydrate, so that they can be given regularly without fear of ill effects. Most important of all, the agent is chemically pure. Another feature they possess; they dissolve rapidly and regularly, and their flavour is agreeable; patients take them with pleasure. But not alone in affections of the throat are they to be recommended. In affections of the nervous system, depending or aggravated by derangements of the gastric nervous membrane, in *mal de mer*, gastralgia they will also be found of signal service. The anæsthetic action of the cocaine can be readily ascertained by personal trial. Dr. Bridger, B.Sc., Paris, writes:—"I have tested the pastils on myself, and find they possess a very marked anæsthetic effect on the tongue, mouth, and throat; they ought to prove of use in the class of cases for which they are recommended.

Reviews.

The Artificial Cultivation of Vaccine Lymph. By JOHN DOUGALL, M.D., F.F.P.S.G. Glasgow: Alex. Macdougall, 1886.

Vaccinia and Variola: a Study of their Life History. By JOHN B. BUIST, M.D., F.R.S.E. London: J. & A. Churchill, 1887.

THESE essays show what has been as yet done in the direction of the cultivation of the specific contagium of variola. Since the discovery of the bacilli of anthrax, and the various other now well-known pathogenic bacteria associated with the infective diseases, pathologists have been actively at work in the attempt to obtain pure cultivations of the organisms associated with those different exanthematous diseases which manifestly depend upon the presence of a contagium vivum. Pure cultivations in liquid and solid media, as employed by Pasteur and Koch, have enabled us to isolate some germs as, for instance, that of tubercle; but as regards variola the practice of inoculation from animal to animal has been an unscientific and the only method of cultivation, the animal itself being the cultivating apparatus. An attempt is made in these books to determine the bacteria form in which the contagia of vaccinia and variola exist in the materials which are capable of reproducing those diseases by inoculation; and further "to discover a method by which the vaccine contagium may be cultivated apart from the animal body in some medium or media not otherwise zymotic, the method to be such that the contagium may by means of it be multiplied to an indefinite extent in successive generations, and that the product after any number of such generations shall prove itself of identical potency with standard vaccine lymph." Dr. Dougall, in concluding his essay, sent for competition to the Grocers' Company, admits that his results do not fulfil the terms of success in solving the above problem. He has failed to cultivate vaccine lymph in artificial soils, and he infers that this failure arises, not from imperfect sterilisation, bad seed,

improper modes of sowing, too high or too low temperature during incubation, wrong methods of incubation, too long or too short periods of incubation, but from some defect in the soil; in short, from the want of some peculiar zymotic pabulum or constituent absolutely essential for its reproduction.

Dr. Buist concludes his summary of results as follows:—
 “Standard vaccine lymph, carefully propagated as at present, is therefore, in my opinion, the best and most convenient material that can be obtained for vaccination. My observations appear to show that when it is taken from a typical Jennerian vesicle, it is a material *in the contagion of which no second principle can possibly reside.*” These essays throw much light upon the conditions of life of the micrococci and diplococci found in and cultivated from vaccine lymph, and it is to be hoped that the authors will not be discouraged by the fact that they have not as yet entirely succeeded in one of the principal objects of the investigation.

R. SHINGLETON SMITH, M.D.

Manual of Hypodermic Medication. By Drs. BOURNEVILLE and BRICON. Translated from the second edition, with additions, by ANDREW S. CURRIE, M.D. Edin. London: H. K. Lewis. 1887.

THIS volume, in its original form, has achieved such notable success on the Continent, that we can only cordially welcome an English edition of a work which has given a great impulse to hypodermic medication, and has done much to advance the science of therapeutics. Three hundred pages on this subject would appear to be more than the method demands, inasmuch as few drugs are commonly given by means of the syringe. Morphia, ergotine, atropine, and ether, complete the hypodermic armamentarium of the great majority of medical practitioners, but a perusal of this work will indicate to what an extent other drugs, in addition to those, may be made to do good service when introduced by way of the cellular tissue. As regards the operative procedure the authors call attention to a practice, which is not unfrequently followed, of injecting into the *substance of the skin*, and not into the subcutaneous tissue. We have often seen the needle introduced slowly and very obliquely, so much so as not to pass into the loose cellular tissue beneath the cutis; when this is done we observe, besides the pain and resistance offered to the needle, as well as to the passage of the piston down the cylinder, an elevation of the epidermis, closely resembling urticaria spots, and leaving behind, sometimes, a superficial scar. We have always found that a rapid introduction of the needle is by far the best, and that little time need be occupied in forcing down the piston; the needle should be withdrawn with equal rapidity, the whole proceeding occupying only one or two seconds, whereas we have often seen each stage of this simple proceeding occupy considerably more time than need be taken by the whole.

The authors specially mention hypodermic tablets. These tablets are composed of an alkaloid combined with a small quantity of sulphate of soda; they are readily soluble, are stable, and always ready for use in emergencies. We have had considerable experience of these tablets, and can bear testimony to their efficiency as well as to their convenience. It is well known that solutions of all kinds are liable to undergo chemical change, and to deteriorate from various causes. Formerly we found that a morphia solution which acted well at first

gradually became unfit for use, and gave rise to excessive and protracted vomiting, probably from the presence of apomorphia; such vomiting as this rarely follows the administration of morphia in the tablet form. In order that hypodermic medication may be utilised, some such mode of preservation of the drug becomes a necessity, otherwise it is not at hand when required, and cannot be obtained without loss of time in cases where time is of value; and it is precisely in these cases when rapid absorption is desired that the hypodermic method becomes of the greatest necessity. Few practitioners would keep a series of freshly prepared solutions always at hand, whereas they may only be very occasionally required; hence the necessity for, and value of, these prepared tablets, which are likely to do more than much precept in aiding the extension of hypodermic medication.

We think that a word of caution as regards the dose of active drugs given hypodermically is not unnecessary. On three occasions we have seen patients in peril from this cause: in one case, one-third of a grain of morphia; in another case, from one-sixty-fifth of aconitine; and in a third, from one-fifth of pilocarpine. The drug once given cannot be removed again, and can only be counteracted by antidotes of a more or less uncertain character. We doubt if it is ever wise to administer aconitine by injection; if given in sufficient dose to affect the disease at all it is not unlikely to entail considerable risk from its action on the heart.

This book gives full details with regard to the drugs in every-day use: these are for the most part accurate and reliable. We notice the following sentence, which appears to be the exact reverse of what is intended:—
 “Pilocarpine is chiefly indicated in those cases where it is desirable to check or diminish excessive salivary or sweat secretion.” As regards the hypodermic use of many of the drugs mentioned, we can only endorse the following paragraph, which follows over thirteen pages on the different forms in which quinine and its salts may be administered hypodermically:—
 “In conclusion, injections of quinine salts should only be practised in cases of urgency, or where there is a difficulty in administering it per os or per rectum.” We think that the same remark might be applied to the hypodermic use of many drugs here mentioned, e.g., antipyrine, bromide of potassium, iodide of potassium, salicylate of sodium, etc., neither do we see any advantage in injecting sulphate of magnesia, seeing that it was sometimes irritating and commonly unsuccessful. We regret to find that parenchymatous injections, “do not come within the scope of our subject” (p. 178). Much interesting information is excluded under this plea, although the translator has alluded to the use of solutions of iodoform, phenol, iodine, and camphor, in pure vaseline as suggested by M. Meunier, of Lyons. It is to be hoped that future editions of this book will give full details of much work chiefly by French observers on which evidence of utility is now steadily accumulating.

R. SHINGLETON SMITH, M.D.

Manual for the Physiological Laboratory. By VINCENT DORMER HARRIS, M.D. Lond., F.R.C.P., and D'ARCY POWER, M.A., M.B. Oxon., F.R.C.S. Eng. Fourth Edition. Baillière, Tindall, & Cox. 1888.

WE congratulate the authors of this book on the rapidity with which they are called upon for a new edition, and on the improvements which they accomplish with each revision.

It contains fourteen chapters on Practical Histology; eight on Physiological Chemistry, and six on Practical Physiology. Much new matter has been introduced, but not to the extent of burdening the student with descriptions of methods which are altogether beyond his scope. The experience of many years' teaching has enabled the authors to provide for the student exactly what he wants, and we think that he who works under their guidance cannot fail to obtain a complete and accurate knowledge of the various branches of Practical Physiological work. With regard to the testing of apochromatic objectives we presume that the name "Drysdale," on p. 10, is intended for that of "Dallinger," whose results coincide with that here given. On p. 8 we observe what has frequently been repeated in text books, but is seldom done, and is altogether unnecessary, that "to use an immersion lens the mounted specimen must be sealed with marine glue, gold size, or other cement which is not soluble in cedar-oil." We confess that if this were a necessity we should rarely use the oil immersion objective; but as it is not necessary to flood the object with oil we have never found any inconvenience from an omission of the above precaution. We are glad to see an appendix on the preservation of normal and pathological museum preparations, also one on bacteria staining.

R. SHINGLETON SMITH, M.D.

A Practical Treatise on the Diseases of the Rectum. By ARTHUR COOPER, F.R.C.S. London: H. K. Lewis, 1887.

ANYBODY studying this little work, with the object of acquiring information denied him in any ordinary surgical text-book, will be disappointed. This is to be regretted, as there is ample room for a comprehensive handling of the subject on which it treats, and with the author's reputation and experience the task should be an easy one. His description of the general symptoms of rectal diseases, and of the methods of examining, is eminently lucid and practical, and equally interesting is the chapter on hæmorrhoids. The majority of surgeons, we think, will scarcely agree with Mr. Cooper when he tells us to operate in cases of strangulation where the hæmorrhoids have reappeared after reduction. Operative interference during the inflammatory stage is to be avoided whenever possible, on ordinary surgical grounds, and the author should be more explicit as to the methods of reduction, and the means to prevent a return of the hæmorrhoid. An anæsthetic surely is not always necessary, and much can be done by means of a wedge pad and strapping to keep under control a restless pile. The ligature is recommended above all other procedures; the only specified reasons over the clamp and cauterly being greater efficacy and less hæmorrhage. The objections we have found relating to the ligature are weighty. The pain which it inflicts is severe beyond compare, and we have not found difficulty at any time in the use of the clamp. Recurrence is not more frequent, the bleeding rarely of any but salutary consequence, and the patient's pain steadily decreases from the first. The instructions in the use of the clamp are not well explained, and much of the success of the operation depends upon manipulative details. Suppositories are useful adjuncts which find no place in this chapter. Not a word is mentioned regarding Mr. Whitehead's revival of excision, which is now so commonly practised. The work is well written, of a convenient size, and thoroughly practical in character, and the faults are of omission rather than commission.

ROBERT JONES.

The Evolution Hypothesis: a Criticism of the New Cosmic Philosophy. By W. TODD MARTIN, M.A., D. Lit. Edinburgh: James Gemmell.

THIS work is a criticism of Mr. Herbert Spenser's Philosophy, as expounded in his "First Principles." "My purpose," the author says, "is to deal with the theory as it undertakes to formulate the entire cosmic movement within the knowable—as it aims at the unification of all knowledge." Mr. Spenser defines philosophy as "completely unified knowledge," and seeks to attain to that unification through a universal application of the doctrine of evolution. Those who are interested in Mr. Spenser's philosophy will find all his positions dealt with by his critic in a very masterly way; but we confess that both the philosophy and the criticism are very dry reading, just about on a par with the philosophy of the unconditioned; and our impression is that Mr. Spenser's "First Principles" is a book not very widely read among medical men. Paradoxical as the statement may appear, there are, however, some little-read books which have much more influence than widely-read ones. A few of the conclusions in an abstruse book get currency and have great influence, just because few care to go to the original and see the arguments on which they are based. We believe that Mr. Spenser exerts great influence in that way, and that by no means for good. When he leaves philosophy and comes to such a subject as sociology or education his order of thinking is of a very different kind. Evolution as a working hypothesis has taken such fast hold of the scientific mind that it is not likely soon to be dislodged; and it is the only defect in Dr. Todd Martin's book that he several times goes out of his way to attack evolution as a scientific principle. We shall best estimate the true position of evolution by comparing it with embryology. That science traces the evolution of the sentient being from the primordial cell to the fully-developed adult. Among other things it unfolds the law according to which one nervous function is added to another till the highest development of mind is reached. In doing so, we may note in passing, it can no more separate between mind and matter in the adult man than it can between life and matter in the nomad with which his existence began. There is no break in the chain. The doctrine of evolution was simply a tentative application of the laws of embryology to the whole organic world. Topsy's answer to the question "Who made you?" was "'Specks I grewed,'" a reply which was considered evidence of her extreme wickedness. Scientific men began to think that growth might be the law of all organic nature, with a like result in the estimation of a great many well-meaning people. Nevertheless this application of the law of growth has proved wonderfully fruitful in bringing order out of confusion. But neither embryology nor evolution explain the innate causes of the sequences they describe. Take the case of the development of a human being. "If we follow the biologist through his long story, what does he do towards touching the mystery of genesis, or help us to conceive how a little thing, shaped like a frying-pan, and so small you can scarcely see it with the best microscope, shall carry over the shape of the paternal nose, the colour of his whiskers, and even his mode of thinking, for sixty-odd years?" If the embryologist does try to answer the question, and explains (?) to us that "an integration of matter has taken place giving rise to a definite coherent heterogeneity," we reply: That may be all very well, but to our certain knowledge the real antecedent of the man in question was a being like himself—his father. Further,

the likeness of the child to the father is only fully seen in the adult condition—a consideration which leads us to notice a favourite fallacy among certain reasoners. Dick, the Sutherlandshire Naturalist, had in his room a sketch of a classic statue of a Greek boy, so placed that the eye at the same time fell on a hideous picture of a monkey, and the naturalist, pointing to each in succession, used to ask in triumph, “Could *that* have come from *that*?” Now in point of fact the Greek boy did come from something very much uglier, for of all ugly things on the earth or under it, a four-months foetus is the ugliest, and such the Greek boy once had been. But whatever the intermediate stages of the genesis may have been, a legitimate generalization of experience is that the true antecedent of all life is one like unto the latest and most perfect development of life—even man—a conclusion which sounds very like an affirmative answer to a very old question, “Have we not all one Father; hath not one God created us?”

There is another aspect of the evolution question which it appears to us has not hitherto been given its due weight. All evolution implies a previous involution, *ex nihilo nihil fit*. You cannot roll out unless you have first rolled in. There must be not only energy, but energy at a higher potential within a finite area than outside of it in order that actual energy may be manifested in doing work. We have shown elsewhere¹ that science points to the beginning of the cosmos being an existence characterised by a very high potential of energy. A dissipation of part of the energy allowed matter as we know it to come into existence, and the energy remaining in it to be manifested as motion, heat, light, etc. Evolution as describing the history of the inorganic cosmos is essentially a progress towards dissolution. It is progress from a higher to a lower potential, tending towards the dead level of uniformly diffused heat. The passage from the inorganic to the organic is an impassable one through any known or conceivable law of energy. As Sir H. Roscoe recently remarked, although the chemist can produce by synthesis the products of organization he cannot produce organization itself, because protoplasm is a structure, not a combination; and, we may add, a structure of a different order of architecture from anything in the inorganic world. Starting with the physiological unit the history of evolution is again one of dissolution. The unit which gives rise to the differentiated units forming either the vegetable or the animal kingdom must have had a higher potential than they. It is again a progress from the higher to the lower; it is the conversion of the potential into the kinetic or actual; it is the doing of work, and work means dissolution. It is again the verdict of science that all things end in death. In the paper referred to we have suggested the hypothesis that the coming into existence of the physical cosmos involves as its correlative the existence of a spiritual one which will abide when the physical one has passed away.

There is yet another consideration. In the history of the evolution of this earth the gradual penetration of light through the surrounding cloudy element exercised a most important influence on the beings inhabiting the earth. It led to the differentiation of the function of certain cells, and to the gradual formation of the eye. The environment developed the function; but the most important part of the environment was not terrestrial but cosmic, and it would have been a profound mistake to seek the antecedent of light

in anything on the earth. When at last the clouds and mists rolled away, and the sun appeared in the sky, there was a complete apparent break in the law of continuity. There was no terrestrial antecedent out of which the sun could have been evolved. More than that, the presence of the sun at once started a variety of changes, chemical and vital, which had never occurred before. The law of continuity seemed set at naught more than ever, and order could only be restored by taking into account a cosmic evolution as well as a terrestrial one. But if the sun had no terrestrial antecedent why should such be sought for Jesus Christ and Christianity? Why should not the dim moral light of earlier ages, and the outshining of moral beauty and grandeur in Jesus Christ, have been the outcome of a cosmic evolution a portion of which alone can be seen? The present is a time when opinions and doctrines of every kind are thrown into the crucible. It would be well if teachers of Christianity would not be in too great haste in declaring what belongs to the kernel in Christianity, lest they be found contending only for the shell. A person to be trusted and imitated is a different thing from a dogma to be believed on authority. It is against this last that the scientific mind revolts. Christianity and science can never really interfere because there is the same kind of difference between them as there is between food and the chemistry of food. Chemical science will not fill an empty stomach; food will. Neither philosophy nor science can stay the cravings of our nature, Jesus Christ set forth in the Scriptures will. That in Him is life, and the life is the light of men is a fact to be ascertained by experiment, not by reasoning—an experiment all are free to make. Once the craving is satisfied it is reasonable enough to enquire why it should be so, and we believe that the relations of Christianity to the laws of intelligent being, as unfolded by modern psychology, open up a field of surpassing interest. We may at a future time refer to some of these relations which most closely touch on the domain of psychological medicine.

A. W. WALLACE, M.D.

Die Etiologische Bedeutung des Typhus-Bacillus. Untersuchungen aus dem allgemeinen Krankenhause zu Hamburg. Von Dr. EUGEN FRAENKEL und Dr. M. SIMMONDS. Hamburg und Leipzig: verlag von Leopold Voss, 1886.

THIS book of seventy pages, to which are added three chromo-lithographed plates, is divided into three sections. The first, occupying twenty-seven pages, is devoted to the description of the results of the examination of the viscera in bodies that had died of typhoid fever. The second, occupying only five pages, to the examination of the blood and intestinal discharges of living patients suffering from typhoid fever, for typhoid bacilli. The last and most important part, taking up the remainder of the book—viz., thirty-six pages, is devoted to a description of the results of numerous experiments, undertaken with the object of reproducing the disease in the lower animals. An organism—a bacillus—supposed to be the specific cause of typhoid fever, has been described by Koch, Ebert, and Gaffky, but it is doubtful whether they all described the same organism. Fraenkel and Simmonds confined their investigations in the dead body chiefly to the spleen, and found in it what they call the Koch-Ebert typhoid bacillus, in twenty-five cases out of twenty-nine. In length it is one-third the diameter of a red blood cell. It stains readily in an alkaline solution of

¹ *Provincial Medical Journal*, vol. vi., p. 163.

methylen blue, or in dry preparations in an alcoholic solution of fuchsin. It varies somewhat in size, and, when cultivated at the temperature of the room, produces no spores. There is nothing characteristic in its appearance, or in the plate cultivations. It does not liquefy gelatine, and grows without smell. On potatoes its growth is much more characteristic. Sometimes the bacillus is found in the spleen at the end of the disease, when the intestinal ulcers are healed or healing. This partly may explain the occurrence of relapses. The grouping of the clusters of bacilli in the spleen is said to be quite characteristic. But next comes the weakest part in the chain of evidence, and very weak indeed it is. *The clusters (herde) of bacilli only grow in the spleen after death.* They are not found in the spleen which is removed within 12-24 hours after death, and placed at once in alcohol. But they are readily found in the same organ if kept at the temperature of the room, but protected from external organisms by being wrapped in a cloth wet with sublimate lotion, for six hours or longer. *The bacilli are not found, and cannot be made to grow on gelatine, if the spleen is kept a week or longer, and becomes thoroughly putrid. The characteristic groups are not found in the spleen in other diseases* when it is treated in the same manner. The bacilli were found in the liver in eight cases out of fifteen. In the following complications search was made for the bacillus, but in each case without success—viz., parotitis, lobular pneumonia, lobar pneumonia, purulent meningitis, pleurisy, and retro-tonsillar phlegmon. The second part deals with the important question of the presence or absence of the bacilli in the blood, and in the intestinal discharges, during life. Hein, in 1885, withdrew blood from the spleen during life by means of puncture with a Pravaz syringe, and states that he found bacilli. But the present authors completely failed to find typhoid bacilli, either by microscopic examination or by plate cultivations, in the blood during life. Neither were they more fortunate in their examination of the blood after death. Gaffky searched for the bacilli in the intestinal discharges, but failed to find it; Fraenkel and Simmonds have examined the intestinal discharges in eleven typhoid cases, and have only found the characteristic bacilli in three. So far, then, the question amounts to this: Koch, Ebert, Gaffky, and Fraenkel and Simmonds have each described a special bacillus in typhoid fever, but their descriptions vary so much that it is doubtful if they are speaking of the same organism. That last described is not found in the blood, either during life or after death; it is not found in the spleen or other viscera *immediately* after death, but only after about twenty-four hours; and, although it is unquestioned that the intestinal discharges are the chief means of propagating the disease, this special bacillus was only found in them in three cases out of eleven. But the latter part of the book, dealing with experimental work, requires a little more consideration. It must suggest to us, either that the typhoid bacillus has really been found, notwithstanding the above improbabilities, or that a disease having some resemblance to typhoid (and in reproducing human diseases in the lower animals a *close* resemblance of clinical symptoms cannot be expected) and producing very similar lesions in the intestine, can be caused in the lower animals by other than true typhoid bacillus. Previously Gaffky had tried inoculation experiments, but without success. The animals used by Fraenkel and Simmonds were rabbits, guinea pigs, and grey house-mice. The injection of a cultivation of typhoid bacilli into the peritoneal cavity of guinea pigs was without effect. Mice treated in

the same way all died, and presented at the inspection swelling of the peripheral lymphatic glands, of the spleen, mesenteric glands, and Peyerian patches. In fresh scrapings of the spleen numerous bacilli were found. In rabbits, injections into the cellular tissue all failed, as also did injections into the lung. Two inhalation experiments also gave negative results. In five cases abdominal section was performed, and the cultivation injected into the duodenum. This also was completely without result. But of thirty-five rabbits treated by injection into the principal vein of the ear twenty-seven died, and these presented the same morbid changes in the viscera as the mice mentioned above. A very good chromo-lithograph is given showing the intestinal ulceration in these cases. In most cases the animals experimented on showed definite symptoms of illness a few hours after the injection, and generally there was diarrhoea. These symptoms usually lasted till death, which generally occurred during the first day: sometimes within three or four hours: occasionally after two to four days. If the animal survived it appeared well in about a week. Many animals survived the injection of a small dose of the cultivation, and afterwards were but little affected by a large dose of the highly concentrated mixture. *The small dose seemed to confer greater or less immunity.* In conclusion, then, although we are far from admitting that any of the so-called typhoid bacilli have yet been proved to have anything at all to do with typhoid fever in the human subject, yet the experimental results of Drs. Fraenkel and Simmonds are sufficiently definite and positive to make us anxiously await the production of further evidence, and till then we must still suspend our judgment.

H. HANDFORD, M.D.

Books which have Interested Me. British Weekly Office, 27, Paternoster Row.

It occurred to the Editor of the *British Weekly* to ask a number of men of mark, in their respective spheres, to give a statement of the books which had formed their most influential environment during their mental evolution. The answers at first appeared as articles in the journal. Twelve of them have been collected into a shilling volume, and a very curious shilling's worth it is. The Hon. W. E. Gladstone leads off with his usual post card, a *fac-simile* of which is given, announcing that Aristotle, Saint Augustine, Danté, and Bishop Butler, are the few authors by whom he has been most influenced. Ruskin has been *most* influenced by Horace, Pinder, and Danté, but adds, characteristically enough, that these are inaccessible to the general reader, and graciously volunteers the information that the following are "good for everybody." Scott, Pope's Homer, Byron, Burns, all good modern French comedies, etc., etc. "I never read English sermons or scientific books"—a statement we find no difficulty in believing. Robert Lewis Stevenson and Walter Besant give replies which will be read with interest. One paragraph from the former we must quote. "The gift of reading, as I have called it, is not very common, nor very generally understood. It consists, first of all, in a vast intellectual endowment—a free grace I find I must call it—by which a man rises to understand that he is not punctually right, nor those from whom he differs absolutely wrong. He may hold dogmas; he may hold them passionately; and may know that others hold them but coldly, or hold them indifferently, or hold them not at all. Well, if he has the gift of reading, these others will

be full of meat for him. They will see the other side of propositions, and the other side of virtues. He need not change his dogma for that, but he may change his reading of that dogma, and he must supplement and correct his deductions from it. A human truth, which is always very much a lie, hides as much of life as it displays. It is men who hold another truth, or, as it seems to us, perhaps, a dangerous lie, who can extend our restricted field of knowledge, and rouse our drowsy consciences. Something that seems quite new, or that seems insolently false or very dangerous, is the test of a reader. If he tries to see what it means, what truth excuses it, he has the gift, and let him read. If he is merely hurt, or offended, or exclaims upon his author's folly, he had better take to the daily papers; he will never be a reader." Weighty words these. P. G. Hamerton, H. Rider Haggart, Professor Stuart Blackie, Archdeacon Farrar, and others contribute each their quota to this singular collection. The character of the writer comes out strongly in some of the communications. Occasionally "very full of himself," as a lady friend of ours used graphically to describe a certain state of mind, best expresses it. Take it for all in all the book is a good shilling's worth, but if the Editor of the *British Weekly* could induce a few leaders in thought and action to make a candid confession as to what *men* have influenced them he might get a book of greater interest still. A. W.

Report of the Trinidad Leper Asylum for the year 1886.
By BEAVAN RAKE, M.D. Lond., Medical Superintendent.

A new infirmary at the asylum was opened in August 1886; it was quickly filled, has been constantly full, and has proved a great convenience in the treatment of the more serious complications, or the after treatment of operation cases. As bearing upon the hereditary nature of leprosy, Dr. Rake gives the following case:—T. B., æt. twenty-eight, was admitted August, 1885, with a six months' history of tubercular leprosy. She brought with her her child, aged eighteen months. This child was plump, healthy, and apparently free from the disease. About the middle of 1886 the child developed leprosy. This child, though it had thus been removed, at the early age of eighteen months, from its unhealthy surroundings, had developed the disease. The disease may have been incubating all this time, the mother and infant having been exposed to the same conditions. "The only really scientific test of the inheritability of leprosy," Dr. Rake observes, "would be for a child to be born of leprosy parents after they have left a country in which leprosy is endemic, and settled in a country free from the disease. If such a child afterwards developed leprosy, it would seem fair to assume its inheritability." In contrast to this case is that of a child of a severe case of leprosy, at the date of its birth, and which was under observation for a year, but no development of leprosy took place. Of seventy-three admissions, fifty-six were males and seventeen females. Thirty-one were Indian immigrants, and twenty-one natives of Trinidad. A high percentage of Coolies continues; probably these find their way to the asylum more easily than Creoles. Fifteen of the seventy-three were re-admissions. Dr. Rake has made trial of the therapeutic powers of ichthyol, but reports that

he has not found it superior to other drugs. "Friction," he adds, "probably plays an important part in its therapeutics." W. B. KESTEVEN, M.D.

Short Notices.

Medical Diaries and Visiting Lists.

THIS is a season for special activity amongst the publishers of diaries and visiting lists, and they are provided in numerous forms to suit the requirements of all kinds of practice.

1. *Smith's Visiting List.*

It was some time in the early fifties that we first made acquaintance with "The Visiting List." We are not sorry to have said good-bye to our old friend. May he have long life and much usefulness before him! We hope all our readers, who are in active practice, possess a copy of the List. How else can they keep their engagements? Besides the list pages, it contains much useful information; but the pages most suggestive of thought are those devoted to the dosage of all the medicines, official and non-official which are now in use. There are nearly eleven pages thus occupied. There are fifty-one remedies on each page; about five hundred and fifty in all. Within twelve years of our entering the twentieth century we have this farrago still in use, the actions of one-twentieth part of which have never been submitted to anything approaching to scientific examination, and new remedies pour in on us still! Farther, it is believed that it somehow fits a man for the care and cure of the sick, that he should not only remember the doses of these five hundred and fifty articles which are supposed to have some curative effect in disease, but also to tell where they came from; if they are organic, what natural family they belong to, and besides all that the proportions used by the manufacturing druggists in making compounds of them. Verily the folly and credulity of man is wonderful! W.

2. *Letts' Diaries.*

The practitioner could not have a better pocket-book than Letts' Diary and Daily Visiting List. It is replete with useful information, portable, and admirably adapted for all classes of practice.

3. *Silverlock's.*

These well-known publishers of medical sundries also produce a useful visiting list made in different sizes, so as to embrace a small and large number of patients. There is a large number to select from.

The Scientific Enquirer: a Monthly Medium for the supply of information on all Scientific Subjects. Edited by ALFRED ALLEN. Vol II., No. 12. London: Baillière, Tindall and Cox.

WE regret that Mr. Allen is obliged, owing to ill-health, to discontinue the publication of this very useful journal, which has served as a medium of communication between persons interested in scientific work. We are pleased to note, however, that Mr. Allen will be able to edit the *Journal of Microscopy and Natural Science*, in which several improvements will be made, and new departments opened.

The Provincial Medical Journal,

JANUARY, 1888.

IN commencing the New Year, and another volume of the *Provincial Medical Journal*, we take the opportunity of thanking our subscribers and contributors during the past year. Numerous letters received have conveyed to us the pleasing intelligence that the paper was favourably received, and well spoken of by critics of known repute. We have aimed at making the paper useful to all classes of the profession, and we believe we have succeeded in a certain measure in our endeavours. During the year 1887 we published many Original Communications of great value, written by specialists, consultants, and general practitioners, and we believe this portion of the journal has been appreciated. In the department devoted to reviewing we have been able to secure the services of thoroughly competent critics, and we refer with some satisfaction to the reviews in this month's issue. The reviews are signed, a feature which we think should be adopted by our older cotemporaries. Matters of interest affecting the profession in all its relations have been treated of by different writers in our Leading Articles, and we can point with pleasure to the stand taken by the *Provincial Medical Journal* to vindicate the freedom of the profession against an oligarchy which sought to dictate what candidates they should elect to the Medical Council. The vast machinery of the British Medical Association was utilized in opposition to the wishes of the members in that election, and had not the *Provincial Medical Journal* existed, we should have been silenced. The Council of the British Medical Association acted precisely as the Council of the Royal College of Surgeons of London are now acting. The *British Medical Journal*, pledged to neutrality, violated its compact. We had to fight the Association staff, and though unsuccessful, we vindicated a great principle. In our Annotations we have noticed many details of minor interest. The great value of the Notes on New Remedies has been testified to us by numerous correspondents. These notes are written by one well acquainted with the newest products, and who has exceptional opportunities of estimating the value of them. Under the heading Periscope we have been able to give a survey of what has been done in nearly every civilised country, so the busy practitioner can in spare moments pick up useful hints, and obtain, as it were, a bird's-eye view of the general literature of medicine. During the coming year we hope to introduce other improvements, so as to make the journal even more valuable than it is now. The journal is run on independent lines; it belongs to no *clique* or party; it does not favour one section more than another, and it is well deserving of support.

THE advertiser of a patent medicine quotes PLATO'S "Meditation on Immortality" to attract attention to his cure-all. Poor PLATO! Churchmen on behalf of the prophet might well invoke "the prayers of the congrega-

tion," for this is an immortality he did *not* meditate upon. "O blessed health!" . . . wrote the author of "Tristram Shandy," and this same mimic of matters medical apes him. Yet these are trifles. The mind which will assert that what is in fact simply a saline aperient, will eradicate or cut short almost all the ills that trouble tribulated man, will surely not hesitate to borrow the inspired writing of classic genius for the means of saying, go. But this article is not concerned with advertisements—directly, at least; it is with what they suggest, for their number and variety give conclusive proof that their purpose is a large one, that the concoctions or compounds to which they apply have a very general use, and it is to this we would more particularly refer—this blind faith in them by a large body of our general public, which surely evinces a reprehensible want of reflexion on their part. The matter of health is very properly regulated by instinct in the lower animals, but when instinct is overruled by the dominant force of reason, as in man, it does show the *perverseness* of his nature that he should still follow the primary form of intelligence. Why is it that man will not apply the same arguments in reference to his physical well-being, and draw the same logical deductions therefrom that he would if reasoning upon any other single matter? Because, though health be the whole soul of his existence, the loss of it is never calculated upon. Consequently when such a calamity overtakes him, as it may overtake anyone, his faculty of reason vanishes before it, and, like those of a drowning man, his actions become impulses, prompted merely by the instinct of self-preservation—possessing nothing but faith, he will now clutch at the ideal straw which most hopefully flatters his unreason with returning health. The age of miracles, at least the scientific belief in them, has gone, yet there clings to the learned and unlearned alike an astonishing faith in the impossible. Let the empiric appear upon the scene at this juncture, offering a remedy, in words which intelligence and healthfulness smile at, and he will be believed—only let him enshroud the cure in a little mystery, and shout its wonders with sufficient assurance, and it will most certainly be tried. "The longer I live," wrote the clever, though occasionally petulant wife of CARLYLE to a friend, "the more I am certified that men, in all that relates to their own healths, have not common sense." As a broad statement this may be accepted; first, for an already given reason, and in the second place, as WILLIAM CULLEN wrote, because "neither the acutest genius nor the soundest judgment will avail in judging of a particular science in regard to which they have not been exercised;" and he proves this by saying: "I have been obliged to please my patients sometimes with reasons, and I have found that any will pass, even with able divines and acute lawyers. The same will pass with the husbands as with the wives." Again, as another famous medical man, the author of *Religio Medici*, said: "There are a set of heads that can credit the relations of mariners, yet will question the testimonies of St. PAUL"—heads with ears more open to rhetoric than to logic. Amidst such

a humanity the professional charlatan must always find abundant employment. HOMER by the mouth of SARPEDON has it that "ten thousand fates of death do every way beset us, and these no mortal may escape nor avoid," and the most unthinking of unthinking men may verify this every moment of their existence. As rational beings then, is it not a duty to anticipate physical calamity, and reason upon our mode of action under such a probable contingency? It is not necessary that we should exercise our judgments specially upon medical science for this purpose, it is not even desirable; but it is both necessary and desirable that we should do so upon the professors or practitioners of this science; a duty simplified when our judgments are limited to the legitimate exponents of it—for surely we must believe that a profession of men specially devoted to the study of what concerns our physical being, knowing all the traditions of their profession, learning all the available knowledge in it, and in the constant exercise of that knowledge—surely we must believe that that profession ought to know most about health, and ought to be best qualified to deal with the morbid variations of it. But we so seldom reason innocently now-a-days that a simple truth rarely strikes us, and this view of the medical profession is a strange one to many. Given one of these unexpectedly attacked by sickness, then the charlatan at hand, volubly vaunting the imaginary and miraculous powers of his one remedy, arrests first the attention, then dupes the reason. What is this remedy—of what does it consist? It may be the original prescription of a legal practitioner, which served its purpose in the instance of this man's own person, who, imagining he has discovered a marvel, unscrupulously hastens to make a monetary use of it, for our country owns no law to prevent him so doing. The nostrum of such a man reminds one of an ignorant novel-reader, who perfectly unacquainted with even the elements of composition, much less having a knowledge of character, or the ability to conceive a plot, reads a story, in the course of doing which he finds an incident which makes him laugh heartily. Straightway he goes and retails this incident to his first acquaintance, in the belief that it will so act on him, without considering, or failing from ignorance to choose, the selfsame circumstances under which it affected himself. It is here where the necessity for educated and practical experience show themselves in medical men—in the ability to judge the moment and the man. Professor GAIRDNER, of Glasgow, once said that "Treatment is an application of common sense, under scientific discipline, to all the circumstances of the case." *To all the circumstances of the case*—for, were all constitutions alike, and all diseases distinct and affecting man always in a precisely similar manner, then the diagnosis and treatment of them might be tabulated and placed in every household, capable of being recognised and applied by anyone simply able to read. But most unfortunately for mankind, his ailments are modified by many circumstances, and seldom admit of uniformity of treatment. This demands an additional gift even from the trained practitioner—a gift upon which the

late Dr. JOHN BROWN, of Edinburgh, thus dogmatises:—"No amount of scientific truth, the most accurate and extensive, can in medicine supersede the necessity of the recipient of all this knowledge having, as RICHARD BAXTER says, by nature 'a special sagacity'—a naturally searching and conjecturing turn of mind." In practice, therefore, medicine must ever remain more of an art than a science, but with science for its basis it must be progressive, progressive in exactness. When the skilful members of a skilled profession then, have so much difficulty in coping with disease, it surely requires no effort of thought to illustrate the absolute foolishness of trusting to others, whose want of knowledge is only equalled by their want of scruple, and to confide in preparations, the only guarantees of which are the assertions of advertisers, plainly unprincipled in their object. But again, many people attempt to rectify their indispositions by aid of quack medicines, who are influenced largely by mistaken notions of economy—they grudge the necessary though by no means exorbitant medical fee. Penny wise and pound foolish people there will probably always be, but they might accept the trust of the author of *Sesame and Lilies* as authoritative upon the point: "So of doctors," he says, "they like fees no doubt, ought to like them; yet if they are brave and well educated, the entire object of their lives is not fees. They, on the whole, desire to cure the sick, and if they are good doctors, and the choice were fairly put to them, would rather cure their patient and lose their fee, than kill him and get it." This again is but an echo of what was written long ago by a physician himself, Sir THOMAS BROWNE: "I desire rather to cure his infirmities than my own necessities. Where I do him no good, methinks it is scarce honest gain, though I confess 'tis but the worthy salary of our well intended endeavours. I am not only ashamed but heartily sorry, that besides death there are diseases incurable; yet not for my own sake, or that they be beyond my art, but for the general cause and sake of humanity, whose common cause I apprehend as my own." Thus spoke a true disciple of HIPPOCRATES, who regarded four qualities as indispensable in every good physician—Humanity, Probity, Learning, Sagacity—which qualities are becoming recognised more and more daily, as those which govern the intentions of the profession at large.

AMONG the social evils of the day, a foremost place must be accorded to the thoughtless indiscriminate doings of those people who persuade themselves that the mere act of giving is being charitable. No course of action is more pregnant with bad results, more insidiously mischievous, more demoralising, more destructive of independence of both feeling and character, than indiscriminate charity. It is not charity, it is merely casting money into an abyss; for it is swallowed up, it disappears and no good results. The charity of the day consists not in seeking out and helping the poor, but in giving to all and sundry who will accept, giving alms to all who simply plead poverty. No care is taken to ascertain or prove that the recipients are genuinely

poor, that they are worthy of help. All workers among them unite in telling us that no section of our population are more independent, more proud, more strongly averse to betraying poverty, than the real poor, those who are reduced to want, to starvation and misery by the inevitable force of circumstances. Such people have to be looked for, they do not put themselves forward. In the looking for these, lies the kernel of the whole matter. Visiting means trouble, labour, disagreeableness perhaps, and so an easier way of satisfying conscience and avoiding exertion is to give the money, leaving to others the visiting—the finding out of people who will accept the *dole*. This is not charity, it is merely playing at it; there can be no charity when there is no definite object, no exact purpose to be fulfilled. When no steps are taken to ensure that such gifts are properly applied, that they find their way to deserving subjects, there is bound to be abuse and misapplication. The most cursory examination of the working of our almost innumerable so-called charitable institutions shows this to be the rule to an alarming extent. It is not too much to say that in the majority of our free institutions actual poverty is a barrier, almost a disqualification to being received. The increase in these institutions in the United Kingdom during the last forty years has been hundred-fold; in London alone, forty years ago there were 73 institutions, to-day there are 252; in the whole of the United Kingdom there were only 293, while to-day there are 1316! Of all these institutions there is not one which is not appealing to-day for more funds, more money to spend in giving away things for nothing; year by year these institutions have been more hardly pressed. That they are spending all their funds is no more than true, but upon whom and for what purpose? Not upon the poor alone! The reason is that the number of recipients has increased, the number of people who, anything but poor, are yet so lost to self-respect, to honest independence, as to have no scruple in accepting “charity.” During the whole of these forty years the country has been increasing in wealth, and yet there are a thousand-fold more people who are ostensibly poor. The truth is that they receive every encouragement, they are positively invited to come. We have been engaged in the examination of the reports of fifty of the leading London hospitals, and fifty of the leading provincial hospitals and institutions, and in all, during ten years only, the increase has been steady and enormous, but in an infinitely greater ratio than that in which the population of the country at large has increased during the same period. After sifting and weighing all the facts contained in these reports, we are forced to the conclusion that each of these institutions is engaged in rivalry to all the others, as to which can *spend the most money*, and show the *largest number of applicants in the annual report*. It is simply impossible to gainsay these facts. The question of hospitals is only one section of the matter, but it is that which most concerns our profession. There are many causes bearing upon this which space does not permit being referred to. One cause, however, which we commend for

the consideration of the profession, is the extreme readiness which so many medical men have in giving their services to all and sundry gratuitously, if only they are given through some professedly charitable institution. This is one factor in the case, but it is not a slight one by any means. The consequence of such a state of matters is bad, not only for the medical profession, but for the country at large. The people are rapidly becoming pauperised—their independence is being destroyed, their moral feelings are becoming blunted, and the disposition to provide for themselves is necessarily eradicated—but besides this, a class of people is being created who live upon other people, so to speak, without any effort on their own part, who become hypocritical, shamming, plausible hangers-on to those who do not take the trouble to consider to whom they are giving. The chief offenders, we feel bound to say, in encouraging this state of things, are the clergy. In this we feel sure we will be supported by most of our profession. The idea is encouraged that there is no need to be provident, no need to lay by for the day of sickness, but wait till that day comes, when help can be begged for, or application made to some *institution* or *hospital*. The idea is fostered that these institutions are for the public generally, and not for the poor especially.

W.

THE working classes are at length beginning to realise the fact that there is something very unsatisfactory to themselves in the present mode of club (medical) practice. They begin to observe, in the first place, that they do not get the best men to accept such appointments; in the second, that the value of their treatment is exactly in proportion to their payment; and in the third place, that they are bound, under penalty of losing benefit, to submit themselves to the treatment of the club doctor, whether he be an able man or not. A working-man expressed his opinion thus: “Ah! for a penny a week we only get penny a week medicine.” This is indeed true. But a working-man, who happens to be ill and not getting on, and feels that he would like to seek other or more skilled advice, he naturally thinks it hard that by so doing he should not only have to pay for this advice, but at the same time lose all pecuniary benefit from his club. He pays so much regularly in order to receive help when *unable to work*, and not to support a particular medical man. He considers that he should have the right to consult any medical man he chooses. This is only fair and right. The power to grant or withhold benefit, however, lies almost entirely in the hands of the medical officer of a club, who thus possesses a means of punishing any member who goes past him to consult another. A case tried in a Staffordshire County Court a few days ago has a most important bearing on the matter, and will serve as a warning and a precedent. From the facts supplied to us we learn that a young man of good character and steady habits became affected apparently with lumbago, and consulted the medical officer of his club. After a fortnight’s disablement, finding no

improvement, he consulted the medical officer of another club, who treated him for eight weeks without apparent benefit. Finding still no improvement, he went to the County Infirmary, where he was relieved, but was found to have more serious mischief at work than ordinary lumbago. After a week at work, he again became disabled, and applied to his club. Here, however, although he received medicine, he was refused a certificate on the ground of *shamming*. He then applied to a gentleman practising near, who treated him for a short time with varying benefit, and then sent him to consult a very eminent surgeon in an adjoining town, who also treated him with the same result. His means being now exhausted, and deprived of all club money, he was compelled to apply to the Union medical officer, who treated him for a time, until on receiving a communication from the *medical officer to the patient's club*, he suddenly refused to give him any further treatment. To crown all, the poor fellow, now entirely disabled and reduced to want, was expelled from his club as an *impostor*. Being advised, he brought an action in the County Court, when, on hearing all the evidence, the Judge decided that he was not an impostor, ordered all arrears to be paid, and the man to be reinstated. It was pleaded that this was a case of persecution, simply because the poor man sought other medical advice. The attempt to prove imposture rested entirely with the two club surgeons; but the circumstance that neither of them discovered that the man was an impostor until they learnt that he had gone elsewhere was significant; and the fact that neither of them discovered any imposture until after they had finished treating him was more significant, and virtually settled the case. One of the surgeons was shown to have given medicine to relieve an ailment which at the same time did not in his opinion exist. The Judge, in summing up, termed it a paltry case, and gave judgment for the plaintiff, with full costs, which, as the clubs had arraigned counsel and a string of medical witnesses, were very considerable. We believe this case stands alone in the history of club practice, and we hope it will for ever remain an isolated case.

Annotations.

“Forsan et hæc olim meminisse juvabit.”

THE PETITION OF THE LONDON COLLEGES RE MEDICAL DEGREES.

THE Royal College of Physicians and the Royal College of Surgeons, of London, have at length formulated their official petition in reference to degrees in medicine. The colleges desire to have the power of conferring the degree of B.M., B.S. and M.D. If this petition be favourably received by Government the Apothecaries' Society will be left out in the cold. The spirit of monopoly is manifest all through the petition, and we feel sure that no Government will sanction such a scheme as the one proposed.

PRESCRIBING MADE EASY.

A CORRESPONDENT has forwarded us some cuttings from a publication, edited by a well-known medical man, asking our opinion on the propriety of this method of prescribing. We give the samples sent us:

TALMUD.—Wash the feet with Blue Gum Tree or Iodoform Soap night and morning, change your socks frequently, and dust on your feet, after washing, a little of Woolley's Sanitary Rose Powder. Internally, take fifteen drops Fer Bravais, after your meals, in water, thrice daily.

W. L.—We advise you to live generously, and, in place of your alcohol, to take with your meals Boköl, which, as a pure and nutritive malt beverage, will do you good. Take, also, after your meals, a dessertspoonful of Thomson's Cod Oil Cream (Dublin-street, Edinburgh), as you evidently require such a lung-tonic and general nutrient. Clothe warmly all winter in the Sanitary Wool Clothing such as is made by Messrs. E. Ward & Co., of Bradford.

BOLSOVER.—The St. Jacob's Oil may do much good in a case such as that you describe. It is a most excellent liniment, and has proved serviceable in our hands.

MOTHER SEIGEL.—1. Try applying hot dry salt in a flannel bag or stocking; and sleep in woollen gloves. 2. Give plenty of fat with starchy foods—such as Marshall's "Tritola," W. Polson's Corn Flour, and like dietary.

The method has this merit of simplicity: the drugs, foods, etc., recommended are all to be found in the advertisement pages, and the advice appears to be meant to encourage their use. As to the propriety we hardly think there can be any need of our giving our opinion. It rests with the Medical Council to decide the point whether such a system is professional.

AN ARTIFICIALLY-PRODUCED RABIES.

DR. PEYRAUD describes in the *Union Médicale* the biological effects of the essence of tansy. The injection of two drops of the essence of tansy causes in the rabbit the most sudden and violent convulsions. The convulsive movements are extremely violent. There is grating of the teeth, biting the tongue, salivation sometimes bloody, blanching of the mucous membranes, evacuation of the bladder and rectum, and rapid spasmodic respiration. A slight excitation will excite a spasm, as in strychnia poisoning. The sense of hearing is over-sensitive. Consciousness is apparently not lost. These convulsions last from fifty to sixty minutes, and, if the dose of the drug has been too large, the animal may die of asphyxia. During this convulsive period the animal bites at everything that comes within his reach, even the ground and his own paws. This biting, with the convulsive manifestations, makes the attack look very much like hydrophobia. After the convulsions comes a period of coma, lasting two or three hours, during which the animal appears insensible to all excitations. The lesions produced in these cases are subpleural hæmorrhages and hæmorrhagic infarction in the liver. Dr. Peyraud calls this "tansy" rabies. In a note presented to the Academy of Sciences, Paris, November 21st, 1887, Dr. Peyraud gives us further particulars on the affection. The paper is published in *Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, 27th November, 1887.

THE COMPOSITION OF SEWER AIR.

THE results of the experiments of Professor Carnelly (Dundee) and Mr. J. S. Haldane, on the air of buildings and sewers, if confirmed by further experimentation, will produce a revolution in current medical opinion. The authors publish the following paragraph:—"The results of these researches will perhaps tend to mitigate some of the terror with which we have come to regard sewer air. Sewer air has been commonly supposed to be loaded with micro-organisms, whereas it turns out to be some of the freest air from mud-organisms that can be found. It may be answered that it is not a matter of quantity but quality. There may be very few germs, but they may be deadly ones. Doubtless they may be, but until we have some reason for supposing that this is the case, the presumption is that they are no more hurtful than other germs which are flashing about everywhere." They then attack the prevailing opinion that typhoid may be, or is, caused by sewer air. "What is the supposed evidence?" they ask. "We may dismiss at once as absolutely worthless collections of cases in which something has been found wrong with the drains in a house where a case of typhoid has occurred, or where the patient has been found to have sniffed at a sewer grating or ventilating pipe shortly before his illness. What one would require to know is, whether the proportion of cases occurring amongst those most exposed to sewer emanations is greater than in those less exposed." In reply to the above we may say that all who are exposed to sewer air do not contract disease, this we assume will be granted. It is very significant, in our opinion, of the ill effects of sewer air, that in houses where sewer air has been admitted, the general health of the inmates has deteriorated; when the sewer air is excluded, in same houses, the inmates improve in health. Few would willingly live in houses in which sewer air entered freely. Microbes and germs are not the only factors in the causation of disease. Herein lies the weakness of the researches above referred to.

THE REGISTRATION OF THE BRUSSELS DEGREE OF M.D.

THE medical graduates of Brussels University can now register their degrees by the payment of £2. Since 1868 some six hundred have presented themselves, but it is not known how many have passed. Still, it will be a nice little sum towards the expenses of the Medical Council if they all register their degree.

THE MEDICAL COUNCIL.

THE Medical Council commenced its session on Nov. 22nd, and it may not be unprofitable to summarise its proceedings. After the address of the president, John Marshall, F.R.C.S., the case of Mr. Partridge was considered, and then referred to the Dental Committee. A bust of Sir George Paget was presented to the Council, and a report on the subject of unqualified assistants gave rise to a very prolix discussion, involving a great waste of time and money.

The case of Mr. Henry A. Allbutt took up the sittings on Wednesday, Thursday, and part of Friday, resulting in a decision that Mr. Allbutt's name should be erased from the Medical Register. The Dental Committee reported adversely to Mr. Partridge, and his name is also to be erased from the Dental Register. The Society of Apothecaries applied for sanction to institute a diploma in Public Health, but on the ruling of Mr. Mackenzie the Council were unable to sanction this application. A report on the registration of foreign degrees in medicine was received and agreed to. A subject most interesting to the Council took up almost the whole of Saturday. This related to the payment of the representatives. A report was presented on income and expenditure, which was referred back to the committee for further consideration. The registrar's remuneration was increased by £100 a year. Mr. Millar has so well discharged his functions that few will object to this outlay. Mr. Teale proposed a resolution that it be referred to the Executive Committee, to consider under what circumstances a medical practitioner would render himself liable to the censure of the Council by the employment of unqualified assistants. Mr. Teale said that his object was to insure notice being sent to all registered practitioners, so that they might not plead ignorance of the wishes of the Council. Mr. Orme had been reprimanded by the Council, and pleaded that he was not aware of the action of the Council against unqualified assistants; he was told to go and sin no more. This was not a brilliant session fraught with great results, but we think it has been one not altogether fruitless.

ARMY MEDICAL RANK.

THE Secretary of State for War has made a very important concession to the requisitions presented on the subject of relative rank, by directing that in future whenever a medical officer's name appears in the *London Gazette*, on appointment or promotion in the department, his corresponding military rank shall be announced, together with his departmental rank. This letter marks a departure acknowledging the justice of the agitation raised by the British Medical Association, the corporations and colleges over the question of the abolition of relative rank.

A VIRUS DESTROYER.

DR. MACCALL thus describes his virus destroyer:—"The composition of the cones in the "virus destroyers," sample of which you have seen, will be nitrate of potash ten parts, and corrosive sublimate two parts. The composition, however, is not the main point; I only chose corrosive sublimate because it is the strongest at present known, and will keep without risk or loss. The main thing is to have an antidote at hand for instant use. They can be made cheaply, and be in the hands of everyone; and for the poor, the police could carry them and be instructed in their use. At present it is the delay that is so fatal before aid can be got, and in many outskirts, etc., no help is near. Their use is not meant to supersede

medical advice, which could be sought as hitherto, but the sufferer would then be treated with the virus probably destroyed, and not as now, after it has been absorbed. A dog bite is usually a superficial scratch or tear, and not a sharp puncture; and even if the canine teeth be inserted deeply, the saliva gets mainly or entirely rubbed off and left on the surface. The lunar caustic still used is decomposed into chloride, and so rendered inert. Setting aside extreme cases (which I believe are attended with least risk on account of copious bleeding), in by far the majority of cases the "virus destroyer" would destroy the virus. Full directions would be given with each, and instructions that after use a doctor should at once be sought. The *moral* effect, too, of the use of these would be great, as Mr. Rotherham truly says, many of the deaths arise from fear, and I have no doubt that in those fatal cases, where even the parts bitten were excised, either it was done too late, or the bad result was due to mental impression."

A PRIZE FOR A MEDICINE CABINET.

PRACTITIONERS who dispense their own medicines find it very convenient to have a lock-up cabinet, that will hold a well-assorted stock of drugs, besides instruments and the various utensils required for dispensing purposes. Some of the cabinets in the market are favourably reported on by medical men, but they do not appear to be as perfect as could be desired; there is room for improvement in design and construction. As medical men are likely to know what form such a cabinet should take, and what drugs and instruments it should hold, Messrs. Richardson and Co., Leicester, offer a prize of £5 5s. for the best design. The following are the conditions:—

1. Sketch required, showing cabinet open and shut.
2. A list of medicines must be appended.
3. A list of instruments, utensils, must also be furnished.

Special attention should be given to compactness, whilst at the same time elegance must be aimed at. Competitors must send their designs under a *nom de plume*, on or before March 1st, 1888, to the office of the *Journal*. The name of the successful candidate will not necessarily be published,

TWO IMPORTANT MEDICO-LEGAL CASES.

THE following cases illustrate the perils of practice:—In one case Dr. Latty was charged with unlawfully signing a certificate, under which the complainant was sent to the County Lunatic Asylum. The case was dismissed without the defendant being even called upon. The certificate was signed in 1882. Dr. Latty must have been put to unnecessary expense, apart altogether from the worry incident to all legal proceedings, and unfortunately he has no redress. The other case, of Dr. Stevens, presents some rather novel features. Dr. Stevens attended Mrs. Kitchener in her confinement in 1884. She died from scarlatina; the husband when applied to for Dr. Stevens' account, sent a letter, in which the following words appeared:—"I shall never pay him unless the law compels me, and that I do not fancy it

can, as I could more easily indict Dr. Stevens for manslaughter." Dr. Kitchener attributed blame to Dr. Stevens in visiting his house after coming from a scarlatina patient. The case came before Justice Hawkins, who decided that the letter was privileged, though no imputation rested on the professional character of Dr. Stevens. Mr. Kitchener wrote the letter honestly, and there was no evidence of malice. This is a very important case for general practitioners, and is well worth forming the subject of discussion at some of our societies:

THE MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

THE last meeting was held on December 7th, when the chairman, Mr. Ernest Hart, gave a retrospect of the progress of the society during the year now ending. During the year different members received payment, the aggregate sickness being over 500 weeks, and entailing an expenditure of £1600; the various claims varied from one week to one year. It was gratifying to know that although the claims had been very numerous, they were fewer than those allowed for by the actuary, Mr. Neison. The reserve capital now amounted to nearly £21,000; of this £20,000 had been invested in first-class securities. One factor which greatly added to this was the very small cost of management. The whole of the work of the managers was done without fee or reward. Over 100 new proposals had been received during the year, and the society has over 800 effective members on its books, with an annual income from premiums of £9,000. Full details and tables can be obtained from Mr. Radley, secretary, 26, Wynne-road, Brixton, London.

IRISH MEDICAL SCHOOLS AND GRADUATES' ASSOCIATION.

WE were unable to publish in the December number an account of the general meeting of this now important Association, which took place on Wednesday, November 23rd, 1887, at 49, Berners Street London. The following members, among others, were present: Sir Thomas Crawford, K.C.B., Director-General A.M.S., President, in the chair; Professor Yeo, Professor A. Macalister, Drs. Gilbert Smith, Macnaughton Jones, Phillips (Reading), Dickson Smyth, R.N., Brigadier-Surgeon Alexander, Drs. Waring (Brighton), Gaven, and Stewart and Abraham (Honorary Secretaries), etc.

The Council reported further proceedings, with reference to the exclusion of those holding Irish medical degrees and the higher diplomas of the K.Q.C.P. and R.C.S.I. from English hospital appointments. Professor Yeo, on behalf of the Council, moved (1) that "the name of a newly elected member shall not be entered on the roll until the first subscription be paid;" and (2) "that the second paragraph of Rule XI be altered so as to read as follows: 'There shall be two other Association dinners each year, at such times and places as the Council may determine.'" The Secretaries reported that the number of members in the Association

had now reached 515. A vote of thanks to the President for his assiduous and valuable services to the Association was proposed by Professor Yeo, and seconded by Dr. Jones, and carried unanimously. A vote of thanks to the General Apothecaries' Company was also passed for the use of their premises.

In the evening the members dined together at the Holborn Restaurant, Sir Thomas Crawford in the chair, and Sir B. W. Foster, ex-President, as Vice-chairman. A telegram was received from Dr. Bridgwater, President of Council of the British Medical Association, regretting his absence as a guest. After the usual loyal toasts, the President proposed "Our Guests," which was responded to by Professor Pettigrew, F.R.S., and Dr. McVail, of Glasgow, members of the General Medical Council. Dr. Macnaughton Jones then proposed the toast "The Universities and Licensing Bodies," coupling with it the name of Professor Macalister, of Cambridge (President-elect of the Association). The toast of the evening, "The Irish Medical Schools and Graduates' Association," was ably given by Professor Struthers, of Aberdeen, and Professor Jacob, of Dublin, replied. Professor Humphry, of Cambridge, gave "Our Chairman." The proceedings were enlivened by songs sung by Mr. Payne, Mr. Baby, and Dr. Macan. Amongst the other guests present were Mrs. Garrett Anderson, Professor Galloway, and Dr. Donald MacAlister.

New Materia Medica.

Sutherlandia frutescens.—This drug has recently been sent over to this country from the Cape of Good Hope as a remedy for cancer. It consists of the foliage and stalks of the plant, which is a leguminous shrub, bearing bladdery thin-shelled pods, something like those of bladder senna. On this account it is known under the name of the Cape bladder senna in English gardens, where it is sometimes cultivated on account of its large scarlet flowers. At the Cape of Good Hope the powdered leaves and roots have long been used in diseases of the eye, but its use as a remedy for cancer appears to be of recent introduction. It is reported that the drug will shortly be tried at the Brompton Cancer Hospital.

Hydrobromide of antifebrine has recently been prepared by a London chemist, with the view of its possible value in cases in which a high temperature is accompanied by delirium, and experiments as to its value are stated to be in progress.

Sulphibenzoate of sodium is the name of the last new antiseptic. According to M. Heckel (*Comptes Rendus CV.*, p. 896), it is prepared by dissolving sodium benzoate in a strong solution of sodium sulphite. It is said to be very soluble in water, and to be absolutely innocuous to human beings, even if taken in large doses. It has been tried in the Hospital of Saint Mandrier, and it is reported as the result of the clinical experiments conducted there, that a solution made by dissolving four or five grams in a litre of water, is superior to carbolic acid as an application to wounds, and that it may be compared in value to the salts of mercury without having their poisonous properties, or to iodoform without its disagreeable odour. The physical and chemical properties of the compound have not yet been published.

Schleichera trijuga.—The oil of the seeds of this sapindaceous tree has recently been introduced into Germany under the name of macassar oil. The tree is common in the East, from India to Macassar, and the oil is used as a remedy for the itch. In Germany it is recommended for its stimulant action in diseases of the scalp.

Bidens bipinnata, a composite plant which has long been used in the United States by irregular practitioners in the treatment of asthma and bronchial catarrh, and is locally known under the name of Spanish needle or beggar's tick, is now mentioned in the *Therapeutic Gazette*, p. 756, as being recommended by Dr. C. R. Gaul, of Jacksonwald, Pa., in the treatment of hay asthma. In this distressing complaint he is said to have employed a decoction of the plant with extraordinary success.

A new mydriatic alkaloid is stated to have been obtained from *Ephedra vulgaris*, a plant of the natural order Gnetaceæ, by M. Kinnosuke Minra. It does not paralyse the accommodation for near vision.

New Remedies.

Phenacetin is the new and more convenient name which has recently been given to acetiphenetidin or acetyl-amido-phenol. The properties of this substance have now been published more fully (*Pharm. Centralhalle*, Nov. 24, p. 583). It is in the form of a powder, of a faintly reddish tint, is odourless and tasteless, dissolves with difficulty in water, is rather more soluble in glycerine, and is more freely soluble in alcohol, especially when heated. It is insoluble in either acid or alkaline solutions, and does not appear to dissolve either in the acid juice of the stomach or in pancreatic extract. It seems rather remarkable, therefore, that when administered to fever patients in doses of 0.3 to 0.4 gram, it should invariably produce a marked antipyretic effect, all the more as that according to Professor von Bamberger, doses of 0.5 to 0.7 gram administered to healthy persons produced hardly any effect.

Antipyrin is stated by M. Dupuy to have proved valuable in the treatment of sea-sickness. He gave to some persons, who had previously suffered much from sea-sickness, three grams daily of antipyrin for three days previous to embarking, and for three days following. Others continued to take the medicine throughout the voyage, and all of them crossed the Atlantic without suffering from sea-sickness. This action of antipyrin is confirmed by M. Ossian Bonnet, who found it effective in sixty cases which occurred during a voyage to Buenos Ayres and back. The dose required was variable; in most cases 1.50 gram was sufficient, the complete effect being produced in about ten minutes. In some cases the dose had to be repeated, but it was never necessary to give more than three grains to produce cessation of the sickness within an hour. In cases in which the sickness was so incessant as to prevent absorption; one grain of antipyrin hypodermically injected was found to be quite effectual.

Naphthol, or more correctly β -*naphthol*, is stated by M. Bouchard (*Comptes Rendus, CV.*, p. 702) to be less poisonous than was previously supposed, and in the pure state to be non-poisonous in much larger doses than are required to produce valuable antiseptic effects in the system, as for instance in the intestinal canal. Experiments have been made with cultivations of certain bacilli, in order to determine the dose necessary to produce marked antiseptic results. One of the pathogenic bacilli chosen for this purpose was one that secretes pyocyanine, and another was a species taken from the intestines of rabbits, and which secretes a green fluorescent matter. It was found that β -naphthol added to a cultivation of the first-named bacillus, in the proportion of 0.40 to 1000 grams, retarded the multiplication of the microbes, and prevented the formation of the coloured secretion, while if used in the proportion of 0.66 gram to 1000 grams, the development of the microbes entirely ceased. The proportion of β -naphthol (0.40 gram) producing this effect was found to be equivalent to 0.025 gram of biniodide of mercury, 2 grams of carbolic acid, 1.6 gram of creosote, 1.27 gram of iodoform, 2.7 grams of iodol, and 1.51 gram of naphthaline. It was found that the lethal dose for a rabbit was 3.6 grams per kilogram of body. This proportion in the case of a man weighing 65 kilogrammes would be nearly 250 grams, whilst the quantity required to produce perfect antiseptis in the intestinal canal is estimated at only 2.5 grams daily; even when injected in the form of a 1 per cent. solution in alcohol, glycerine and water, the toxic dose was found to be 0.40 gram. per kilogram of

weight, or equal to 26 grams for a man weighing 65 kilograms. If, therefore, the full dose to procure antiseptis of the intestinal canal were absorbed from the starch, it would only amount to one-tenth of a poisonous dose, and such absorption is very unlikely owing to the sparing solubility of the drug.

Cocaine has been the subject of several careful investigations, which have thrown considerable light upon its possible purity or otherwise. There is now no doubt that cocaine exists in the leaves in company with other bases. One of these named, *hygrine* is a fluorescent body, and is therefore easily recognised; another, named *cocamine* by its discoverer, Dr. Hesse has as yet been found only in the small-leaved or Peruvian coca. Another named *cocaidine*, by the same chemist, has been detected in the broad-leaved or Bolivian coca. This base is amorphous, has a very bitter taste, causes a very transient sensation of numbness, and does not appear to irritate the eye. None of these bodies have been proved to possess anæsthetic properties, and until such is the case, should be removed from the cocaine used in medicine. As a test of the absence of amorphous alkaloid, the cocaine should be free from any marked odour, and the solution of hydrochlorate, when liquid ammonia is added to it, should not produce a milky, but should give rise to a precipitate of minute crystals from a clear liquid.

Saccharin has formed the subject of some experiments made by Mr. E. J. Millard, with the view of determining whether it possesses an anti-fermentive property, if added to the more commonly employed ferments. In these experiments a 0.2 per cent. solution of saccharin was used. In the case of pepsin it was found to possess very little retarding action, and the same was the case with pancreatin with relation to its action on casein, but saccharin interfered materially with the amylolytic property of pancreatin, ten times the amount of the latter being required to produce the ordinary result; but it was found that if sodium carbonate were present in sufficient amount to neutralise the saccharin, no appreciable retardation took place. In the case of diastase, saccharin was found to exercise a retarding action, so that twice the usual amount of diastase was required to effect the same amount of starch; when however the saccharin was neutralised, a slight increase of diastatic power was observed. On papain the retarding effect was very slight. With respect to its action upon moist fibrin, Professor Salkowsky had previously shown that the antiseptic effects of saccharin are greatly lessened when it is neutralised, so that saccharin, like benzoic and salicylic acids, is much more active than its salts.

Stenocarpine (as suggested on p. 514) proves on examination to be a fictitious alkaloid like hopeine, analyses having shown that the solution sold as a 2 per cent. solution of stenocarpine or gleditschine contains cocaine, atropine, and a little salicylic acid. (*Therap. Gazette*, p. 756). An alkaloid named gleditschine does, however, appear to have been obtained from *Gleditschia triacanthos* by Dr. B. H. Lautenbach in 1878.

Dr. Randall Hutchinson (*Therap. Gazette*, p. 731) furnishes a contribution from the Laboratory of Experimental Therapeutics at the Pennsylvania University, on the physiological action of *Cimicifuga racemosa*. He arrives at the conclusion that when full therapeutic doses of the drug are taken, it produces a sense of fullness of the head, giddiness, intense frontal headache, dimness of vision, and vertigo, with a feeling of general malaise and aching of the limbs. A reduction of the pulse is a constant symptom after the administration of the drug. In some instances it causes nausea and vomiting, looseness of the bowels, and occasionally purging.

Menthylal forms the subject of some valuable notes in the *Medical Press* (November 2nd, p. 417) by Dr. B. W. Richardson. He considered that its action lies between ethylic alcohol, and ethylic ether. It reduces arterial tension, and by local action excites glandular activity. It does not induce profound sleep unless an excessive dose is given. A fatal dose kills by completely relaxing the muscular fibres of the heart, leaving the heart distended with blood, and the vascular organs intensely injected. It tends to maintain the fluidity of the blood, and may consequently be of service in combination with ammonia. It does not reduce the animal temperature so much as common alcohol. He

believes that it will form a safe and effective anæsthetic mixture in combination with ether. It can be administered either by inhalation, by subcutaneous injection, or by the mouth in aqueous solution. It is quickly eliminated, leaves no serious effects, and does not cause either vomiting or stomachic disturbance. It combines well with ether, amyl nitrite, and many other remedies, and equalises their action by reason of its own solubility. Its chief value appears to be as an hypnotic and anti-spasmodic.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

Labio-Glosso-Laryngeal Paralysis, Occurring Suddenly, from Obliteration of Bulbar Arteries. By M. Richardière (*Journal de Médecine de Paris*, Decembre 4th, 1887).—Laval, æt. forty-five years, was admitted on the 20th of May, 1883, under M. Bucquoi, into the Cochin Hospital, on account of a series of nervous symptoms. The patient had suffered from a similar attack in the previous year for about six weeks, after which time the symptoms gradually passed off. Laval was of a strong constitution without trace of any marked diathesis. At the time of admission into the hospital she was in a dull obtuse condition and seemed to have lost her memory. This state came on suddenly four days previously. Articulation was embarrassed and the mouth was closed with difficulty. Intelligence was perfect; she answered all questions correctly, and had followed her occupation up to the moment of the attack. At the time of her admission she exhibited the complete symptoms of glosso-labio-laryngeal paralysis. The eyes were wide open and movable in all directions, but the eye-lids could not be completely closed. The mouth was open, and from the paralysed state of the orbicularis allowed the saliva to dribble. The tongue was equally paralysed and could not be protruded. The *velum palati* was immovable. Deglutition became difficult, and liquids were rejected through the nostrils. Speech was nasal; articulation difficult and confused. Movements of the limbs were unimpaired. Sensibility was normal. The radial arteries and the aorta presented some indications that they were atheromatous. There could be no doubt that this was a case of labio-glosso-pharyngeal paralysis, the only question was as to the history of its origin. The suddenness of the attack excluded the softening of the bulbar centres as described by Duchesne, the complete evolution of which occupies months, sometimes years, in the successive impairment of power in the muscles. The state of the large vessels indicated the possibility of acute softening from the same condition in the bulbar arteries, of which examples were recorded by Hallopeau. In the present case the obliteration of the bulbar arteries could only have been momentary, as the paralysis had disappeared in the course of a few weeks. The tongue first, then the lips, and *velum palati* recovered their motor power. The paralysis of the *orbicularis* of the eye was latest. In two months from admission the patient left the hospital. It is to be noticed that in this case there was an absence of any affection of the larynx, and non-participation of the vagus. So sudden an attack occurring in full health, together with the rapidity of course of the paralytic symptoms leave only the conclusion that hæmorrhage in the bulb must have been the cause.

A New Process for the Medico-legal Examination of Blood Stains. By M. Ferry de la Bellone (d'Apt) (*Progrès Médical*, Novembre 26th, 1887).—This process aims at uniting in a small volume as possible the largest amount of the blood elements. If the stain be upon linen, fibres are to be teased out with a needle and placed in a tube on a one-thousandth solution of chloride of sodium. The fluid will soon become of a reddish brown colour; this liquid then examined by the spectro-scope will present the characteristic lines of hæmoglobin. For the examination of the blood globules one or two drops of a saturated solution of chloral are to be added to the fluid, when a rose-coloured precipitate will be obtained, the superincumbent fluid is to be recovered with a pipette—a drop of the precipitate is to be exposed on a thin plate over the flame of a spirit lamp. A clear liquid will be separated and may be taken up by blotting paper. The pellicle of coagulum that is left should be coloured with fuchsin, then washed with water. A drop of diluted acetic acid will render the preparation transparent, and the globules will be apparent of a bright red colour. Crystals of hæmatine may be seen if, before adding chloral to the precipitate above-mentioned, dried; a few drops of acetic acid be added, while warm, the crystals will appear as it cools.

An Artificial Serum for the Dilution of the Blood in the Enumeration of the Globules (*Le Progrès Médical*, Novembre 26th, 1887).—M. Mayet, at the sitting of the Academy of Sciences, Paris, on November 14th, gave the following formula:—Distilled water, 100 parts; anhydrous neutral phosphate of sodium, two parts; cane sugar to raise the density of the liquid to 1.085. In this artificial serum the globules of the blood preserve their normal form.

The Fauna of the Grave (*Le Progrès Médical*, Nov. 19, 1887).—M. Magnin has shown the correctness of the popular belief in "worms in the tomb." Naturalists have supposed that bodies buried six or seven feet underground, in closed coffins, must be decomposed by physico-chemical agencies. The exhumations effected by M. Brouardel have shown that the non-scientific opinion is correct, and that dead bodies are devoured by insects at that depth as nearly entirely as in the open-air. The "worms" are the larvæ of insects, some of which were deposited on the bodies before interment, whilst others, derived from the surrounding earth, find their way through fissures in or between the planks of the coffins; the ova having been deposited on the surface of the earth, the larvæ have been attracted to penetrate the soil by the emanations from the body. Certain coleoptera attach themselves to fat, others to thin bodies. M. Magnin infers the age of the interment from the species of insects in the coffins.

Epilepsy of Aural Origin (*Le Progrès Médical*, Nov. 26, 1887).—(*Académie des Sciences*, Nov. 14, 1887).—M. Boucheron pointed out the occurrence of an epilepsy of auricular origin, presenting all the diverse forms of *grand mal*, *petit mal*, and *hystero-epilepsy*. The starting point is an excitation of the auditory nerve, producing a disturbing influence upon the medulla oblongata and brain, in the same manner as the epilepsy described by Brown-Sequard, from irritation of the fifth nerve. One of the most interesting forms of epilepsy is deafness from obstruction of the Eustachian tube. An examination, therefore, of the ear should be instituted at the commencement of symptomatic nervous affections.

On the Twofold Cerebral Action, in Voluntary Movements (*Le Progrès Médical*, Nov. 19, 1887).—At the sitting of the *Académie des Sciences*, Paris, on Nov. 7th, M. Brown-Sequard discussed the grounds of the generally received teaching with regard to the above question. If, urged M. Brown-Sequard, the prevalent notions were correct; if each half of the brain influenced exclusively the opposite half of the body, then every irritation on one side of the brain from the excito-motor zone to the decussation of the pyramids, should determine only movements on the opposite side of the body. M. Brown-Sequard, however, holds (1) that galvanic or mechanical irritation of the internal capsule causes sometimes movements of one or two limbs on the same side; (2) that irritation of the cerebral peduncle, especially in its lower portion, produces more frequently movements on the same than on the opposite side; (3) that irritation of the pons varolii, in its motor portion produces movements on the same side in three-fourths of the cases; (4) that irritation of the anterior pyramids produces movements of the same side nine times out of ten. On the other hand, M. Brown-Sequard states that if after having raised the transverse layer of the pons varolii, the lower surface of the incised portion be stimulated, the effects are the same as in excitement of the upper surface. The movements, indeed, by irritation at the base of the brain, are reflex, and not simply the effects of irritation of voluntary nerve-fibres. If, adds M. Brown-Sequard, the current doctrine were correct, transverse section of one-half of the base of the brain, on the right side for instance, should render impossible the alleged action of the motor centres in the cortex on the right, and cross action should be lost, whereas after this section it is often found that the limbs on the left side manifest more energetic movement than before the division. M. Brown-Sequard affirms that the phenomena of paralysis in man do not support the current theory. He rejects entirely the opinion that the right brain is the source of motor power to the members of the left side, and the left brain to those of the right side.

The Treatment of Phthisis by Inhalations of Hydro-fluoric Acid (*Journal de Médecine de Paris*, Novembre, 29th, 1887).—A report upon a communication to the "Academy of Medicine," upon the above subject, by MM. Seiler and Garein, was read by M. Herard. M. Garcin had submitted to the consideration of the Academy a work founded upon a hundred observations. M. Herard had visited many of these cases, and had investigated for himself the results. He concludes with the statement that hydro-fluoric acid possesses an undoubted therapeutic action when phthisis is not far advanced. Its use, M. Herard adds, is free from inconvenience, is easy of application, and admits of being conjoined with other medicinal agents, and especially with hygienic treatment.

On the Uses of Antipyrine (*Journal de Médecine de Paris*, Novembre 27th, 1887).—Dr. E. de Pradel writes to say that he has

given this medicine in many instances, but that its effects do not come up to the vaunted standard of utility, and that he has ceased to prescribe it except in cases of migraine and neuralgia. If, Dr. de Pradel observes, there be any affection in which antipyrine might be expected to be of service, it is acute articular rheumatism; but in the cases in which he had used it he obtained no beneficial results, and cannot compare, in therapeutic power, with salicylate of soda. In two cases of typhoid fever, its administration was followed by such profuse perspiration, and a comatose condition, that it was withdrawn. "Why relinquish," Dr. de Pradel adds, "our old antithermic or analgesic agents—quinine, salicylic acid, morphia, etc.—for a new and uncertain remedy?"

On the Poisonous Action of Alkaline Chlorates (*Centralblatt für Kinderheilkunde*, November 26th, 1887).—Although as far back as 1885 a fatal case of poisoning by chlorate of potash was recorded, and although in 1860 Jacobi had pointed out that large doses of the alkaline chlorates are dangerous, the opinion that these salts are innocuous has prevailed. In the year 1879 the fatal action of the chlorates was shown by experiments upon animals. This led to a reconsideration of the free use of these remedies in diphtheritic affections. Since then, year after year, occasionally fatalities have been announced. Several instances of the fatal effects of their careless and too profuse employments as gargles, in which large quantities have been swallowed. The principal symptoms have been jaundice, suppression of urine, cramps, coma, followed by death in varying periods. These salts have also been employed for suicidal purposes, also for the induction of miscarriage. On *post-mortem* examination, the kidneys have been found of a dark chocolate colour, loaded with dark blood, the urinary tubes filled with dark cylinders and globules, the urine strongly alkaline, of a dark colour from excess of hæmoglobin and biliary matters. The following case may be taken as an example of the poisonous effects of the chlorates. A—, aged 57 years, suffering from severe acute angina, was ordered a gargle of a three per cent. solution of chlorate of potash every half-hour. The patient was cautioned against swallowing it, but in the course of thirty-six hours he had used fifty grammes of the gargle. Of this a large portion had been swallowed (May 7th). On the following day he exhibited extreme prostration, was enervated, and had a dull, heavy expression of countenance. The face and conjunctiva were deeply coloured with jaundice; the lips and ears presented a greenish-blue discoloration. Vomiting was urgent, sleeplessness and restlessness were observed. The temperature was 96°F.; the pulse soft and small. Great thirst. Suppression of urine; with great effort about six drachms were voided, of a dark brown with greenish shade. In the sediment were large flocculi and coagula, consisting of glittering scales and hyaline cylinders, only a small proportion of albumen. Profuse sweating was induced by woollen wrappings. The suppression of urine continued, and on the 14th day of the same month the patient died suddenly. On *post-mortem* examination the kidneys were found enlarged beyond their normal size, externally they were of a rich brown colour. The pyramids had a dark blackish-brown colour. The tubes were found to be loaded with cylindrical casts and blood globules.

Experimental Researches upon Delphinium Staphisagria, and Delphinine. By Dr. Gauthier, Naples (*Journal de Médecine de Paris*, Novembre 20th, 1887).—Delphinine is an amorphous yellowish resinous powder, insoluble in water, soluble in alcohol, chloroform, and acidulated water. The maximum dose is from one to ten milligrammes in a day. Combined with vaseline, one part to five, it has been used externally as a pomade. Dr. Gauthier gives the following conclusions as to the physiological and toxicological effects:—Its action is primarily upon the medulla oblongata, and subsequently upon the sympathetic system. It produces, at first, functional excitement, then a gradual diminution of the functions, and a complete but evanescent abolition thereof. The analgesia may last for twenty-four hours. The action of delphinine upon sensibility constitutes its most important physiological, and upon this is based its therapeutical, employment. In poisonous doses it acts upon the locomotor system producing incoördination and ataxy, the contractility of the muscular fibres being maintained until the death of the animal. The action of delphinine is upon the heart and circulation, it at first accelerates the cardiac movements and causes irregularity therein. Then occurs a period of more regular action, finally the heart's action ceases in diastole. The modifications of blood tension consist in a temporary elevation followed by a more or less marked depression, accompanied by corresponding modifications of temperature. The effects of delphinine are extended to the respiratory functions by the production of spasmodic action of the abdominal and intercostal muscles, and of the diaphragm, consequent on the augmentation of carbonic acid in the blood. When the tetanic action is at its highest, the animal dies from asphyxia. Death occurs from arrest of the respiration. Vomiting and diarrhoea are caused by delphinine. Upon

the pupil its action on the cilio-spinal centre is seen in this production of myosis followed by mydriasis. In its elimination it augments the secretions. The treatment of poisoning by delphinine is indicated by its mode of causing death. Artificial respiration affords time for its elimination, and the action of other remedies, such as strychnia and atropine. The therapeutic action is exerted in neuralgia affections attended with augmentation of sensibility, such as neuralgia of the fifth nerve. Its preferable mode of use is by subcutaneous injection in doses of one milligramme repeated at intervals of two hours. The external application is useless on account of its non-absorption. [Dr. Gauthier's conclusions correspond closely to the observations of Dr. Launder Brunton—see *Text Book of Pharmacology*, 1887.]

Toxicity of Strychnine (*St. Louis Medical and Surgical Journal*, December, 1887). Choupe and Pinet, who have for some time past been experimenting with the view of determining the minimum of the lethal dose of strychnine administered hypodermically, announce to the Society of Biology of Paris, that they have determined it to be between 0.24 and 0.25 of a milligram (0.0037 grain) to each kilogram (2 lbs.) weight of the animal experimented upon. The kind of animal, its age, etc., seem to cut little or no figure in the general result. At this rate it would take a little over one-third of a grain of strychnine, administered hypodermically, to kill a man weighing 200 pounds.

Summer Diarrhoea (*St. Louis Medical and Surgical Journal*, September, 1887). Dr. Victor Vaughan, in the course of a paper in the *Maryland Medical Journal*, says on this subject—*The first thing to do is to stop the administration of milk in any form.* The ferment is present in the alimentary canal and giving the best milk would simply be supplying the germ with material for the poison. This no-milk-treatment is not by any means a new idea; but the reason for it has not hitherto been understood. Now that we know that a powerful poison is formed from the putrefaction of milk, the necessity for its exclusion must become apparent to all. The food used may consist of chicken and mutton broths, beef juice, and rice or barley water. With this list no difficulty will be experienced in giving the child sufficient nourishment.

II.—NOTES FROM FRANCE.

BY HASTINGS BURROUGHS.

At the Académie de Médecine Dr. Ernest Besnier made an important communication on the malady known as leprosy. For him this affection, instead of being now obsolete in Europe, is still frequently witnessed, especially in the South, and the origin might be ascribed to a special microbe, although it has not been fully determined how or in what degree the malady is transmitted, for the method of transmissibility varies much. In any case man is the only agent by which leprosy is transmitted. He carries it about with him wherever he goes, and no special climate can be incriminated. It is without doubt hereditary, but not to such an extent as might have been believed. Poverty and close huddling together was a very exciting cause; and thanks to sanitary laws, which are now the basis of medical science, the propagation of leprosy is no longer to be dreaded.

The lesions observed in those who are addicted to the consumption of morphia by injection or otherwise have been specially studied by Professor Ball in a case which he had to treat recently. A young woman entered the hospital in order to be delivered from the evil habit. She used to inject as much as thirty grains of morphia daily. She asked that the drug should be immediately suppressed; but in a day or two the collapse was so great that it had to be readministered, and gradually it was replaced by injections of sparteine. The treatment lasted two months, when she seemed to be perfectly cured. However, just as she was preparing to leave the hospital, she died suddenly. An autopsy was made, and the heart was found to be enlarged and fatty, the liver, kidneys, and spleen were in a similar condition; and in the hepatic organ a considerable amount of morphia was found.

In the *Révue de Médecine* Dr. Chauffard recommends a very simple but successful treatment of idiopathic jaundice which has been employed lately in Germany. It consists in enemata of cold water administered once a day. Nearly a quart might be used for young persons, whereas about twice that quantity should be given to adults. The water should be very cold, and retained as long as possible. He cited several cases in which he obtained the most satisfactory results from four to eight days of treatment. After the first two or three enemata the bile returns into the intestine and colours the fæces; the appetite returns, and the patient feels a *bien être*. The pruritus which is so often distressing also yields rapidly. The method of action would seem to be as follows: the extreme cold of the water produces a reflex action on the intestine, which extends to the muscular coats of the biliary ducts, producing their contraction and consequently the expulsion of

the obstruction. It will be well understood that this treatment only applies to the catarrhal form of icterus.

Dr. Fraipont, in an article published in the *Annales de la Société Médicale de Liège*, calls to mind the constant use of iodoform gauze plugs in the treatment of bleeding cavities, and recommends it in obstetrics. He has used it for plugging the uterus in cases of passive hæmorrhage, and has been much pleased with the result. Of course the uterus must be considerably dilated, but such a condition is generally found after abortion, or those surgical operations such as excision of polypus, enucleation of fibroma. The plug might be left *in situ* twenty-four hours or longer, and renewed each time.

Les Archives de Médecine contains a remarkable case of multiplied gangrenous cutaneous patches. A girl of twenty-one, having received a slight wound on the left thumb, perceived a gangrenous patch close to the sore. Other patches soon were discovered on the arm, shoulder, and even on the face. Slight fever accompanied the apparition of each patch; the skin reddened, and soon became covered with a grey spot with yellow points. The slough became detached speedily, and the wound rapidly healed. The treatment consisted in application of a sublimate solution (one per cent).

At the Société de Chirurgie a long debate ensued on the treatment of perforation of the intestines produced by external wounds. Two opinions had their partisans; one was that when the penetration was fully diagnosed the abdomen should be opened, the intestine sought for, and the wound closed to prevent fecal matter from escaping into the peritoneum, while the other was in favour of systematic abstention. M. Reclus said he would be inclined to the latter, or conservative treatment, although he would not deny that sometimes the most heroic method may be called for. The diagnosis of traumatic perforation is very difficult. The tissues of the abdominal wall divided by the instrument close up again, and it is impossible, or nearly so, to say what damage has been done to the internal viscera. Sometimes it has been observed that the knife, or ball, just struck between the folds and thus left the intestines untouched. Such cases have been observed in the proportion of four per cent. As to the immediate signs of perforation, they were obscure and often wanting, and generally it is only when peritonitis supervenes that the fact is discovered. In penetrating wounds of the stomach hæmatemesis may be observed, whereas hæmorrhage from the intestines through the rectum is not often witnessed *au début*. In any case penetration is not necessarily fatal when treated without operation. Statistics have shown that although great damage may be done the patient recovers, and the reason may be found in the fact that stercoral matter is not always present in the intestine, as frequently the person has not eaten for several hours. In conclusion M. Reclus indicated the line of treatment he would follow in penetrating wounds of the intestine. The patient is placed in a position of absolute repose, the external wound washed by an antiseptic solution and hermetically sealed by iodoformised collodion; the abdomen is covered with a good layer of cotton and firmly bandaged with a flannel roller, as after ovariectomy. Subcutaneous injections of a third of a grain of morphia are given, and feed the patient on exceedingly small quantities of milk, beef tea, or wine; thirst will be combated by ice in the mouth. If in spite of all peritonitis is observed laparotomy remains the only resource.

Treatment of gastralgia:

Ext. of coca.....	3 iiss.
Syrup of orange.....	3 i.
Water	3 v.

A tablespoonful every hour.

III.—NOTES FROM RUSSIAN JOURNALS.

BY VALERIUS IDELSON, M.D., BERNE.

On Concentration of Scarlatinal Virus.—At a meeting of the local Medical Society, Dr. J. J. Ostroïmoff, of Arkhangelsk, read an interesting paper (*Proceedings of the Arkhangelsk Medical Society for 1886*, vol. ii., 1887) on the etiology of scarlet fever, whose epidemics condescend to visit from time to time that lonely northern centre of (more or less) civilised life, in spite of all black—or even jet-black—frosts reigning over the vast coasts of the White Sea. The main point to which the author draws attention is the influence produced by “concentration” of the scarlatinal contagion on the duration of incubation on one side, and on the intensity of morbid symptoms on the other. Dr. Ostroïmoff lays down the following propositions:—
1. The degree of “concentration” of the scarlatinal virus shows a marked influence on the duration of period of incubation. 2. The length of the latter stands in a converse relation with the degree of “concentration” of the contagion—in other words, the stronger the “concentration” is (or rather, the larger the amount of the virus is which finds its way into the patient's system), the shorter the period of

incubation becomes; and the more diluted the virus is, the more the period of incubation lengthens. 3. The same holds true in regard to the course taken by the disease. The more concentrated the virus (and, therefore, the shorter the period of incubation) is, the more severe course is taken by the attack of scarlatina; the more diluted the contagion is, the milder the form is which is assumed by the affection contracted. Therein the explanation of the fact should be sought that "in the beginning and termination of epidemics of scarlet fever almost rudimentary forms alone are observed." To quote some of the facts on which Dr. Ostroïmoff's assertions are based:—A lady with her only boy, aged three, visits a house where two children have died from a malignant form of scarlet fever a couple of days before, and attends the funeral service of three hours' duration. On the third day her boy falls ill with severe scarlatina, to die two days later. Several hours after his death the lady calls on a district police officer to speak about some formalities in connection with her deceased child's burial. On the seventh day after her visit the officer's only son, aged eight, develops all symptoms of a mild form of scarlet fever, the attack ending in recovery in about three weeks. Neither the lady's boy nor the officer's have been in contact with any other sources of the infection, except those mentioned above.

[The same subject has been touched also in an able paper of Dr. J. A. Kosmovsky in the *Proceedings of the Arkhangelsk Medical Society*, vol. i., 1885, p. 11.]

Cockroaches in Dropsy.—Dr. J. A. Snejko, of Kaluga, reports (*Proceedings of the Kaluga Medical Society*, part i., 1886, p. 5) a case of anasarca, in which he administered powdered cockroaches in the daily dose of $1\frac{1}{2}$ drachms. Having no idea of the nature of his "medicine," but being quite satisfied with its services, the patient took four additional teaspoonfuls of the powder daily. The diuretic treatment of the kind brought about a marked improvement. Notwithstanding the largish doses used, the drug did not produce any gastric disturbances, or any other unpleasant effects.

Meanwhile, Dr. V. E. Kritchevsky, of Kaluga, recently saw (*ibid.*) a case of general dropsy where powdered cockroaches, taken in the daily dose of three teaspoonfuls, gave rise to gastric disorders, without bringing any beneficial change in the patient's state. Cockroaches are an ancient anti-dropsical remedy of Russian peasants. Into the scientific medicine the drug was introduced (almost simultaneously with maylilies, adonis, and clay) by Professor S. P. Botkin, of St. Petersburg. Some physiological and clinical facts concerning the subject may be found in Drs. Bogomoloff's and Tchernysheff's works.—*Vide the London Medical Record*, June, 1884, p. 250.

Hydrops Adiposus or Chylosus.—In the *Meditsinskia Pribavlenia K' Morskoi Sbornik* (Medical Supplement to the Naval Review), February, 1887, p. 140, Dr. M. A. Lüklin, prospector to the Cronstadt Marine Hospital, contributes a case of a rather rare morbid form, described by some authors (Quincke, Klebs, Luecke, Friedreich, Boegehold, Winiwarer, Marcet, Ormerod, Curnow, Wilks) under the name of "Hydrops Adiposus or Chylosus" (and apparently noticed also by Rokitsansky, Oppolzer, Morton, Hoppe-Seyler, Marshall Hugues, Manson, Bergeret). Dr. Lüklin's case refers to a highly emaciated peasant woman, aged seventy, in whom simply "ascites" was diagnosed during life. At the *post-mortem* examination the peritoneal cavity was found to contain thirty fl. pounds of a sallow, turbid, watery liquid of alkaline reaction, while the (extremely contracted, almost entirely destroyed) great omentum, transverse colon, duodenum, pancreas, and pylorus, were studded and matted together with numerous scirrhous nodules. A portion of the ascitic fluid, after a day's standing, gave a reddish deposit, which under the microscope proved to consist of (a) shrunken red blood corpuscles, enclosed in a fine-meshed network of coagulated fibrin; (b) large round corpuscles, with a fine granular protoplasm, closely resembling the colostrum-spheres; and (c) scanty flat epithel-cells undergoing fatty degeneration. The fluid standing above the precipitate remained as turbid as before. It was then mixed with some ether, and left alone for two hours, by the end of which time there was found on the surface a thin, whitish, cream-like layer, consisting of fatty drops of varying sizes, and of margarine crystals in the shape of fine needles grouped in small bunches. Discussing the question from which source the fat could come forth, and be admixed to the peritoneal effusion in his case, Dr. Lüklin arrives at the admission that he had to deal with a case of "ascites chylosa"—that is, with the case of transudation of a stagnated chylus from the mesenteric and other abdominal lymphatic vessels, under the influence of a constant pressure produced by the tumours on the lumbar and celiac lymphatic plexus. Another theoretically possible source—a wholesale fatty degeneration of histological elements of the malignant new growth—is here excluded by the fact that the carcinomatous nodules were hard, and did not show any sign of disintegration. The subject under consideration possesses a real practical interest, since some authors (Boegehold,

etc.) are going even so far as to assert that an "adipose" character of any effusion (as established by aspiration) points to the presence of a malignant tumour (carcinoma or tubercle), and that, therefore, a puncture may supply us with an additional diagnostic sign of no small value.

Congenital Absence of the Penis.—In the *Vratch*, No. 24, 1887, p. 487, Dr. Vinogradoff, of Bolshië Berezniki, Simbirsk Government, records a rare case of a peasant boy of seven, who, when brought to the author on account of inguinal and scrotal intertrigo, was found to have no penis at all. The scrotum and testicles were quite normal. At the anatomic site of the root of the penis, at the upper end of the scrotal raphe, there was present a small urethral opening surrounded by a normal scrotal skin. He passed urine in a good jet, but by the termination of each micturition some urine streamed down along the scrotum (hence the skin-disease in the boy). Through the integuments there could be felt the cavernous portion of the penis, measuring two or three centimetres downwards from the urethral slit.

On the Physiological and Therapeutical Action of Trimethylcarbinol.—Trimethylcarbinol is a tertiary pseudo-butyl alcohol (prepared by Professor Bittleroff, of St. Petersburg, in 1864). It is a thick, oily liquid substance, possessing a pleasant camphor-like odour, and easily soluble in water in all proportions. In 1867 Professor A. J. Danilevsky, of Kharkov, has carried out first physiological experiments with the substance on frogs and men, and has discovered that "trimethylcarbinol diminishes irritability of nerve-cells of the mental centres, without causing any initial excitation of the parts." In 1885 Drs. H. Thierfelder and von Mering also stated that the drug manifested a hypnotic influence on rabbits. Quite recently, at the suggestion of Professor Danilevsky, Dr. B. M. Shapiroff (*Vratch*, No. 17, 1887, p. 359) has undertaken a long course of experiments on frogs, rabbits, dogs, and men, in order to more minutely examine the biological effects of trimethylcarbinol and thus to prepare a more or less reliable ground for its use as a therapeutic agent. The conclusions reached by Dr. Shapiroff may be summed up as follows:—1. *In small doses* (in a hypodermic dose of from 0.01 to 0.05 gramme in frogs, in an intravenous dose of 0.05 to 0.5 in rabbits, and 0.5 to 1.0 gramme in dogs) trimethylcarbinol (a) lowers the irritability of the brain in frogs; (b) lowers the blood-pressure through paralysing the vaso-motor centres in rabbits and dogs; (c) does not show any influence on the pneumogastric nerves. 2. *In middle doses* (in a hypodermic dose of 0.1 gramme in frogs, and in the internal dose amounting to 0.1 per cent. of the body weight in rabbits and dogs) the drug (a) produces an inhibitory action on the brain, causing a transitory general lassitude and immobility in frogs, and a short excitement ("alcoholic narcosis"), followed by general languor, drowsiness, staggering gait, etc., in rabbits and dogs; (b) does not change the cardiac, respiratory, or reflex actions. 3. *In large doses* (in a hypodermic dose of 0.2 in frogs, in the internal one amounting to 0.2 per cent. of the body weight in rabbits) it (a) suppresses the cerebral action, causing a temporary complete paralysis of voluntary movements in frogs and rabbits, and also deep sopor in the latter; (b) in rabbits and dogs, when introduced into a vein or the stomach in a half a gramme or a larger dose, the drug produces a very marked decrease of excitability of the cerebral cortical substance; (c) in frogs, the minimal lethal dose is 0.5 gramme, in rabbits it begins with three per cent. of the animal's weight. 4. *In man* (about 200 observations on patients suffering from various nervous disorders), (a) when given internally, in the dose of five to fifteen drops two or three times daily, trimethylcarbinol lowers mental irritability, and generally alleviates a morbidly-increased nervous excitability (in cases of neuroses, hyperæsthesia, neuralgic headaches, etc.); (b) it does not give rise to any initial excitement. 5. *General corollaries.* (a) Trimethylcarbinol belongs, therefore, to the group of sedative nervine (mainly cerebral) drugs; (b) it may prove of service (i.) in functional (non-organic) cases of mental (cerebral) excitability; (ii.) in cerebral neurasthenias associated with mental excitement; (iii.) in delirium tremens; and (iv.) possibly, in certain forms of epilepsy.

Almost simultaneously with Dr. Shapiroff, Dr. Ekaterina O. Shimova-Simanovskaia, one of the house physicians to Professor S. P. Botkin's clinic in St. Petersburg, has published (*Ejenedelnaia Klinicheskaja Gazeta*, No. 11, 1887, p. 193) a preliminary note on her own experiments bearing on the same subject. The outcome may be condensed thus:—1. *Experiments on dogs.* 1. When given internally, trimethylcarbinol sometimes causes a profuse salivation and increases appetite. In the dose of 0.58 to 1.96 gramme pro 1 kilogramme of the animal's weight, it gives rise to a fleeting excitement with a marked weakness of limbs (especially of the hind ones), which is soon followed by drowsiness and actual sleep. The latter in the beginning is interrupted, but subsequently becomes deeper and quiet, and lasts from one to six hours. 2. When injected under the skin, the drug brings about the same phenomena, but somewhat more rapidly. During sleep (a) the respiration remains quite

equable, but becomes somewhat deeper and slower; (b) the cardiac action is, as a rule, also retarded; but (c) the arterial tension is not altered (at least, when the dose does not surpass 0.804 gramme pro 1 kilogramme); (d) the cutaneous sensibility decreases; (e) as a rule, the temperature remains unaltered, but sometimes it slightly ($0.2^{\circ}\text{C}.$) sinks. When injected into a vein, the drug produces a considerable though transitory fall of the blood pressure with a simultaneous retardation of the pulse—e.g., after the dose of 1.96 gramme pro 1 kilogramme, the pressure gradually returns to the normal level in about two hours. 4. Only in one "very nervous" dog, which had been occasionally suffering from "twitchings" when asleep, the drug induced fairly strong general clonic convulsions (also during the animal's sleep). In the remaining animals experimented upon (the number of which is not stated by the writer), the use of trimethylcarbinol was not accompanied by any untoward accessory phenomena. The maximal internal dose used by Dr. Shūmova was 1.96 gramme pro 1 kilogramme; ditto hypodermic = 1.0; ditto intravenous = 1.2. II.—*Experiments on frogs.* The drug was invariably injected into the femoral sac. 1. In small doses it induces only a fairly strong excitement. 2. In large doses (0.4 gramme) trimethylcarbinol gives rise (after a very short period of excitement, or sometimes without it) to a rapid prostration, with a marked diminution of sensibility, extreme retardation of the cardiac and respiratory organs. The animal remains entirely motionless, and to all appearance lifeless, for about twelve hours, and then gradually but completely recovers. III.—*Experiments on men.* Only two cases are adduced in detail, in which the drug was given as a hypnotic for relieving obstinate sleeplessness. In both of the patients (men) a dose varying from ten to twenty drops invariably produced, within thirty minutes, a quiet, sound, and refreshing sleep of about nine hours' duration. No unpleasant accessory effects were ever observed.

In the *Vratch*, No. 19, 19, 1887, p. 388, Dr. B. M. Shapiroff states that he has recently studied also (in Professor F. V. Ovsiannikoff's laboratory in St. Petersburg) the biological action of another tertiary alcohol, of dimethylcarbinol (which is the tertiary amyl-alcohol obtained by treating zinc-methyl with chloride of propionyl. It is a limpid oily fluid, possessing a pungent odour). The writer has arrived at the following results:—1. When introduced in the dose of 0.001 to 0.005 gramme under the skin in frogs, the drug gives rise to the same phenomena as produced by much larger doses of trimethylcarbinol. The initial period of excitement is either very short or absent altogether. 2. It acts mainly and before all on the cerebral hemispheres, whose action is inhibited and paralysed by the drug; later on, the latter paralyses also the spinal cord, as is shown by the arrest of the lymphatic hearts, the motor centres for which are situated in the cord, as Veliky's investigations have established beyond any doubt. 3. Dimethylcarbinol considerably lowers the arterial tension through paralysing the vasomotor centres. 4. It does not exert any direct influence upon the cardiac muscle. 5. But it acts on the body temperature, considerably lowering it, as some experiments on rabbits have shown. 6. In general, the qualitative biological action of dimethylcarbinol is identical with that of trimethylcarbinol, but the former acts more powerfully and more swiftly than the latter.

To judge from all experimental data published up to the present, the following physiological proposition seems to be justified:—While the chemical group of primary alcohols possesses a stimulant action on the animal system, the group of tertiary alcohols, on the contrary, belongs, as a whole, essentially to the category of inhibitory or sedative agents.

IV.—EXTRACTS FROM SPANISH MEDICAL JOURNALS.

TRANSLATED BY DR. G. CADOGAN MASTERMAN.

Enfermedad de los Buzos (Diver's Paralysis). By Dr. D. Rosendo Pi, Barcelona (*Revista de Ciencias Médicas—Continued from page 571, December, 1887*).—*Phenomena due to Increase of Pressure.*—The first of these is severe pain in the ears, with rumbling and explosive noises, caused by the driving inwards of the tympanum, which occasionally leads to its rupture. The remedy is to equalise the pressure by means of the Eustachian tube, and the diver tries to do this by forced deglutition, which opens its pharyngeal extremity, or when one ear alone suffers, by pressing the corresponding nostril against the valve which projects within the helmet and then breathing heavily. Severe pain is often referred also to the frontal sinuses and the jaws, with a singularly pungent sensation within the nostrils, often followed by profuse epistaxis; and one of the minor troubles is a persistently bitter taste in the mouth and severe headache. All these, however, generally disappear as the pressure within and without the helmet becomes equalised. The sensation of insufferable heat of which the workmen in the Argenteuil cassons complained so much is not felt by the diver, although his body

is generally bathed in profuse perspiration, for the water is usually cold enough to cool the compressed air effectually, in fact, the hands often ache intensely from the cold, and the condensation of the man's breath in the casque greatly interferes with clear vision. They wash the glasses by sucking water through the front valve and spitting it over them from the lips. Another trouble is the excessive secretion of urine, for, although the skin is acting so profusely, it is of course drowned in its own secretion, and the compressed air is so saturated with moisture that the lungs can get rid of none of it, and, therefore, triple duty is thrown on the kidneys.

As soon as the men at the pump have got the right pressure these difficulties disappear, and the diver seems to labour with more energy than at the surface so long as it does not exceed that of three atmospheres, but when the compression is between three and four or greater still an unconquerable desire to sleep often steals over him in a short time, and would soon end in fatal stupor. Therefore, when the diver is working in very deep water he signals frequently with the cord at his waist, and if these jerks cease his companions haul him up with all speed; consciousness often returns during the ascent, or at once when the front disc is unscrewed. At great depths, too, a feeling of suffocation in spite of abundant air is generally experienced, the act of inspiration is of course extremely laborious under so heavy a load and makes every other movement at the same time excessively fatiguing. Another result is hæmoptysis, the interior of the helmet is often bespattered with blood; at the same time coughing is rare and all sense of bronchial catarrh disappears when a moderate depth has been reached; and in spite of the excessive renal secretion thirst is never felt, but, as a compensation, there is much hunger, a quarter of an hour at a fair depth gives a prodigious appetite; and there is another compensation: it is most difficult to take a deep breath from the weight on the chest, but then, the oxygen being so compressed, very slight thoracic movements are necessary to carry on respiration.

Phenomena due to Decreased Pressure.—In returning to the surface all feeling of respiratory oppression rapidly disappears, but there is often troublesome coughing and sneezing, and very frequently bleeding from the nose. Noise and pain in the ears also, from the tympanum being driven outwards, but this quickly passes off as air can escape much more easily through the Eustachian tubes than it can enter them. The same vascular congestion which leads to epistaxis causes occasionally extensive ecchymoses under the skin, that of the abdomen looking as if it had been bruised. The skin, too, sometimes feels dry and scorchingly hot, and this is a serious matter for it is often the first symptom of grave internal mischief. Unbearable pruritus troubles others as soon as the helmet is removed, and severe neuralgic pains are common. M. Rameaux considers that most of the effects experienced on ascending are due to the sudden extrication of gases which had been absorbed under pressure by the blood, and which, according to Dalton's law, would be released effervescingly when that pressure was reduced in the vessels. This has been confirmed by some experiments of M. Bert's on animals; but the latter points out that although true in theory it is small in actuality, the imperfect respiration admitting a proportionately smaller quantity of air into the circulation; and all these effects are generally but transitory. The graver have now to be considered: one is an intense, expansive headache, the pain most excruciating, it feels as if the skull were breaking in pieces, and is sometimes accompanied by symptoms of compression of the brain—difficult articulation, distortion of the mouth, and so on—coming on shortly after the helmet has been removed, but generally passing off as the cerebral circulation recovers itself in about an hour's time, not always, however, ending so simply. But it is the analogous condition of the spinal cord which leads to the most serious and permanent mischief, and in which the danger of too rapidly decreasing the pressure on the surface of the body is most disastrously exhibited. The pathognomonic symptom is an extraordinary pallor and coldness of the surface, the face of the diver when the front disc is unscrewed before taking off the helmet exactly resembling that of a corpse to the eye and touch, and when this is well-marked there can be no doubt as to the gravity of the case. As an example: N. X—, twenty-six years of age, robust and healthy, made a descent in twenty-eight fathoms (four atmospheres) and remained under water for eight minutes, and then returned to the surface feeling nothing unusual, but on exposing his face its aspect at once alarmed the crew who, hastily removing the diver's dress, laid him on a mattress and subjected him to vigorous massage, which is the only treatment they employ in these cases. The integument was cold and bloodless, but he only complained of pain between the scapulae. Respiration got rapidly weaker with rhonchus at each inspiration, all surface sensibility was lost and the face became livid, and the breathing more embarrassed and slower, then general paralysis set in. The rubbing and kneading were, however, continued between three or four hours, when the patient opened his eyes

and seemed to be breathing more freely, this improvement was transitory and he died five hours after his submersion.

Case 2.—J. F—, of the same age as the last, and as healthy as one could be, went down in a depth of twenty-five fathoms (3.6 atmospheres) and came up complaining of pain in one knee. However he shortly descended again and then felt acute pain in his arms; he was very unwilling to try a third time, but his companions seem to have chaffed him with being afraid, and he once more went over the side. He did not stop down so long as usual and was very anxious to get out of the dress, saying it suffocated him, and almost immediately became insensible. He was rubbed for two hours and then recovered consciousness, complaining of aching all over his body. Dr. Pi applied elastic bandages to the upper part of the thighs, which were removed a few hours afterwards at the patient's request, and paraplegia immediately set in, with paralysis of the bladder. This gradually and spontaneously passed off, and at the end of six weeks the man was able to walk, but with persistent numbness and weakness of the right leg.

Case 3.—S. M— was twenty-five years old when he took part in an expedition to the island of Mallorca, in one descent he remained half an hour under water at a depth of twenty-five fathoms, came up and got out of the dress apparently unaffected. But shortly afterwards he felt a pricking pain in the right loin with such weakness in the legs that he was obliged to remain seated, but the bladder was unaffected and in four or five days he felt no more of it. Six years afterwards he was again collecting coral at the same depth and came up in twenty-eight minutes, and in four or five more, just as he had been stripped, the same pain attacked him and was followed by complete paraplegia involving the bladder. In a few hours the pain left him, and was succeeded by dyspnoea which threatened to end in suffocation; this passed off, however, after the chest had been rubbed for some time, and the paralysis also in about forty days, but he never thoroughly recovered the use of his lower extremities.

Case 4.—J. C—, of lymphatic temperament, and aged twenty-six years, was diving for coral off the coast of Bona, on the bank of the Cala Traverse, at a depth of thirty fathoms (4.3 atmospheres). In one of the descents he remained but two and a half minutes at the bottom, and quickly re-ascended. When the front lens was unscrewed the crew noticed a strange alteration in his face, which led them to strip him immediately, to his great annoyance and surprise, for he persisted in saying that there was nothing the matter with him. However, he fainted as soon as he stepped out of the dress, and remained insensible for nearly an hour. He then recovered consciousness, stammered a few words to the effect that he was all right, and lay down in the prow of the boat, when some of the crew commenced rubbing his limbs to avert, if possible, the dreaded paralysis; but in a few minutes pungent pain commenced in the legs, then in the arms, with rapidly increasing dyspnoea, and threatened suffocation. He complained, also, of epigastric pain, but of none in the spine. The massage and friction was kept up for twenty four hours, the crew taking turns at the work, and only then desisting because they had rubbed nearly all the skin off his body. He had temporarily recovered consciousness several times during this extraordinary procedure, and complained of the pain it gave him, and then relapsed into complete insensibility. But his condition getting worse, it was decided to put him in a cot and carry him ashore, and eventually to Bona, a distance of nearly twenty-two miles (thirty-five kilometres), but the poor fellow, as might have been expected, died before they had traversed half that distance.

Case 5.—N. C—, of robust build, twenty-nine years of age, went down to a depth of thirty-nine fathoms (5.6 atmos.), and remained three minutes; when he came to the surface he complained indistinctly of severe pain in the arm and right leg, kept twisting his neck about, and then became insensible. After two hours of the usual rubbing, he apparently came to himself for a moment, shouted loudly to a boy, and then relapsed into unconsciousness. Massage was redoubled, and continued for half an hour afterwards, when he again became sensible, but with complete paraplegia involving the bladder. In three weeks time this cleared off, leaving him, however, with permanent weakening in the lower extremities.

In the sixth case, after an immersion of only eight minutes, severe pain was felt in the calves of the legs, then in the thigh, and speedily followed by complete paraplegia, which passed off, however, after a few days rest in bed.

Case 7.—F. T—, a strong healthy fellow of thirty-six years of age, in one of his descents entered a cleft in the rocks, which led into an immense submarine cavern, the floor of which was at a depth of 186 feet below the surface (4.4 atmos.) He was groping within it for six minutes, then returned to the sea and ascended. He complained at once of

severe pain in the left arm, which soon extended to the chest and the spinal column, with the usual sense of impending suffocation, and was followed by insensibility with general paralysis. The crew had commenced rubbing him at once, and after six hours friction he recovered consciousness, but without being able to use his legs. The next day he was able to crawl about with the aid of a stick, but he was somewhat crippled for a few days longer.

Case 8.—M. B—, of thirty years, went down in twenty-two fathoms (3.1 atmos.), and remained quietly collecting for a quarter of an hour; when he came up he seemed to breathe with difficulty, lay down and fell asleep. When he awoke he found he could neither raise his left arm or leg, but there was not complete paralysis. He declined the usual friction, only asking to be covered up and left alone, and after another sound sleep was quite himself again.

Case 9.—S. T—, diving off the Sardinian coast, remained at a depth of twenty-three fathoms (3.3 atmos.) for half an hour. Directly he reached the deck he complained of severe abdominal pain, and then lost the use of his legs so suddenly that he would have fallen like a lump of lead if two of the crew had not caught him. He complained of no pain or difficulty in breathing, but underwent the usual severe regimen to no purpose. There was complete motor and sensory paraplegia, with atony of the bladder, necessitating catheterism for a month, and another elapsed before he was able to get about on crutches, with permanent paresis of the lower extremities.

Case 10.—C. V—, a healthy man, forty-four years of age, was searching for coral in one of the caverns which run under the Balearic Islands, at a depth of twenty-seven fathoms; he came up in about ten minutes, and was at once stripped, when his face became suddenly suffused and he lost consciousness, and when this passed off there was hemiplegia on the right side. A little later the usual dyspnoea set in, with severe pain in the loins. He was rubbed for six hours, when consciousness returned, but with inability to empty the bladder and to walk. Two days afterwards he came under the care of Dr. Pi, as the only case under his treatment. He found the patient in bed with his legs enveloped in bran poultices, and complaining of severe pain in the lumbar and lower dorsal vertebrae. On the inside of the left knee there was a severe burn from a can of boiling water having been accidentally upset over him, and which he had scarcely felt. There was complete motor paraplegia, but with some sensation left, pricking pain in the toes, and the urine was dribbling away from the distended bladder. Skin hot, abdomen tympanitic, and the tongue thickly furred. The doctor wanted to bleed him, but this was (happily) not permitted, so he prescribed tisanes and fifty grammes (rather over three ounces) of castor oil, and removed the poultices. The oil acted disastrously the next day, for there was complete paralysis of the *sphincter ani*, the urine was left to escape as before, and the distension of the abdomen was somewhat worse.

Two days later, September 1st, the pain had become more severe in the back, so a large plaster of *thapsia* (*Thapsia villosa*) was applied there and another three full ounces of castor oil administered. The next day one is prepared to learn that the patient was delirious, complained of difficulty in breathing, and that the pulse had gone up with a falling temperature (nothing is said about diet, but he was doubtlessly starved on broth and herb tea), the pain however had disappeared. By September 28th control had been regained over the bladder, and to a great extent power in the legs as well. On October 14th large bed-sores were noticed, and an interesting spinal reflex. On palpating the abdomen over the first lumbar vertebrae a wave of nerve-force seemed to pass to the feet, followed by violent trembling of the limbs. In the following month the man was able to get about on crutches, but hopelessly crippled to the present day. The dangerous nature of the work is shown in the following table:—

Number of divers engaged	85
Severe attacks in the superior region of the medulla.....	17
Cases of complete paraplegia.....	23
Deaths	15

To these should be added:—

Suffocated through the breaking of the air tube.....	1
Ditto, through failure in one of the valves of the pump ...	2

The first accident often happens, but if the diver be hauled up immediately he can generally be rescued in time, especially if he has had the presence of mind to close the exit valves, when the helmet retains air enough to last until the surface is reached. The rarer mischance of a valve breaking is more dangerous, as it usually happens when the man is working in very deep water.

(To be continued.)

V.—SELECTIONS FROM THE "RIVISTA INTERNAZIONALE DI MEDICINA E CHIRURGIA."

BY HENRY HANDFORD, M.D.

Decker. Contribution to the Etiology of Gastric Ulcer.—The author has made some experiments on dogs to show the part that eating, or more especially drinking, food at too high a temperature may play in the causation of gastric ulcer. He took two dogs, and gave to each of them, by means of an œsophageal tube, during anæsthesia, small quantities of liquid at a temperature of 122°F., on several occasions during three or four days. The dogs remained perfectly well, and were killed at the end of a few days. In the first was found at the pyloric end, near the lesser curvature, an extravasation of blood about half-inch in diameter between the mucous and muscular coats. In the second there were numerous congested spots, together with an extensive extravasation, and at the pylorus two typical gastric ulcers. The author mentions the case of a man who, by the directions of his medical attendant, frequently drank water at a temperature of 140°, and developed symptoms which could not be explained except upon the hypothesis of gastric ulcer.

Grundzsch. Cases of Total Suppression of the Secretion of Hydrochloric Acid without Carcinoma of the Stomach.—**Jaworski.** Absence of the Secretion of Hydrochloric Acid in the course of Catarrhal Affections of the Stomach.—**Beno-Lewy.** A case of Complete Atrophy of the Gastric Mucous Membrane.—These three authors deal with a subject which has been attracting much attention during the last two or three years. It has been stated that in carcinoma of the stomach the secretion of hydrochloric acid by the gastric mucous membrane ceases. This appears to be to a very large extent true, and the explanation seems to be in many cases, if not in all, that given in the case described by Beno-Lewy—viz., the coincident atrophy of the mucous membrane of the rest of the stomach. But the view that was at first put forward, that an absence of hydrochloric acid from the gastric secretion could be used as a diagnostic means between carcinoma and other affections of the stomach, does not seem to be borne out by further investigations, as the cases narrated by Grundzsch and Jaworski show.

Bernheim. A case of Peritonitis from Intestinal Perforation, followed by cure.—The patient was a boy aged fifteen, suffering from typhoid fever. Convalescence was established about the thirty-ninth day, but on the fiftieth day symptoms of perforation suddenly set in. There was sudden abdominal pain, a rigor, rise of temperature, pulse and respiration, meteorism, vomiting and suppression of urine. He was treated by opium and the cessation of all food by the mouth, and eventually got well.

Wagner. A case of Acute Polymyositis.—The patient was a tubercular woman of about thirty-six. She was attacked with rigidity and pain in the muscles, accompanied by œdema. Notwithstanding the swelling of the skin, the muscular masses felt doughy. Movement was painful. The electrical examination of the muscles did not show any change. She was treated by massage and faradisation, and showed some signs of improvement, but eventually died of asphyxia. After death the muscles were found to be all affected by a special change, giving them a pale red colour and homogeneous appearance, and increased rapidity. Microscopically there were found interfibrillary hæmorrhages, and œdema of the muscular fibres obscuring the striation. In places there were spaces filled with friable masses. Some fibres showed all the stages of cloudy swelling and of fatty degeneration. Elsewhere there was amyloid change. There was also interfibrillary cellular proliferation. The nerves also showed signs of peripheral neuritis. Very few cases of acute inflammation of the muscles have been described, and but little is yet known with certainty of its clinical course. Chronic inflammation and inflammation leading to calcification (myositis ossificans) are equally uncommon.

Prior. Clinical Value of Sulphate of Spartein.—In exceptional cases, about once in four times, it happens that spartein increases the flow of urine in the healthy individual, without the state of the circulation undergoing any appreciable alteration. It is not yet decided whether the diuretic action is due to a special influence exercised by spartein on the renal epithelium. Whether this be so or not, there seems good reason to admit that it is, at any rate, in part due to the action of spartein on the heart. The observations of the author indisputably prove the influence of the drug on the intra-vascular tension. Spartein has given favourable results in the most various forms of heart disease. But it is equally true that in many cases it has proved useless, especially in affections of the myo-cardium. It has been found most efficacious in failure of compensation in valvular disease. Its effects are perceptible within two or three hours after it has been given, and generally pass off in a few hours, sometimes only after two or three

days. When the secretion of urine is diminished in consequence of disturbance to the activity of the heart, the effects of spartein in regulating the cardiac action, and in producing diuresis proceed *pari passu*. The frequency of the pulse diminishes, and at the same time the vascular tension rises. Spartein has not been found to exert any beneficial influence on bronchial asthma. In only one case were ill results noted after the administration of spartein, and that was after thirty grains had been taken during two days. It produced irregularity in the cardiac rhythm, dyspnoea, nausea, giddiness, and weakness in the limbs. The average dose is 1½ to 3 grains three or more times a day. Smaller doses are usually inefficacious, and much larger ones are apt to produce the ill effects noted above. It is stated not to have any cumulative action. Finally the author considers the sulphate of spartein to be useful (1) in those cases of heart disease in which digitalis, which remains the remedy *par excellence*, disagrees and cannot be given; (2) where it is desired to strengthen and regulate the cardiac contraction in as short a time as possible; (3) in cases of astyole, when it produces favourable results without influencing the rhythm; (4) in all cases where it is wished to increase the flow of urine.

E. Puis. The Action of the Seeds of Strophanthus in general, and their use in Diseases of the Heart and of the Kidneys.—The author gives the results of his own observations on the action of the tincture of seeds of strophanthus as a cardiac tonic, diuretic, and anti-spasmodic. The action of the tincture was indisputable in cases of failure of accommodation from valvular disease, in fatty heart, arterial sclerosis, and in kidney disease. The pulse became fuller and stronger, its frequency was diminished by twelve to forty beats per minute, the rhythm improved, the *besoin de respirer* diminished, the secretion of urine increased, and the œdema disappeared in a few days. On the contrary, strophanthus completely failed in ascites due to cirrhosis of the liver, or to chronic peritonitis, as well as in palpitation from anæmia, chlorosis, or nervous disease. Strophanthus, according to Fraser, has the property of increasing the blood-pressure, without at the same time causing contraction of the small blood-vessels, and thus impeding the flow of blood through them, and increasing the work of the heart, as digitalis does. This property is specially advantageous in cases of Bright's disease.

VI.—INTERNATIONAL MEDICAL CONGRESS.¹

(Continued from page 570, December, 1887.)

VII.—DISEASES OF CHILDREN.

A PAPER was read from Dr. William Henry Day, of London, entitled—Some Observations on Headaches in Children, and their Relation to Mental Training.—The writer considered the characteristics of nervous, frontal and neuralgic headache, and the condition known as irritable brain. One form or the other is the first and most persistent symptom of the breaking down which follows the mental over-pressure which now prevails in education, and in the competitive examinations for entrance in every profession and in every branch of the public service. The irritable brain is not infrequently accompanied by myopia, hypermetropia, and astigmatism.

VIII.—LARYNGOLOGY.

Mr. Lennox Browne, of London, read a paper entitled—Recent Views as to the Pathology and Treatment of Tuberculosis of the Larynx.—The tubercular bacilli are generally admitted as a cause of specific laryngitis. Entrance is effected through the air-passages, and they are especially liable to accumulate in the upper parts of the lungs, where there is less respiratory action. The disease is usually secondary to pulmonary tuberculosis, and may be due to infection from the bacilli in the sputa coughed up and inoculating some abraded or unhealthy and irritated portion of the larynx, or the germs may find their way thither through the lymphatic system. The bacilli, like all parasites, act as an irritant, and eventually cause breaking down of the tubercular deposits. They must have an unhealthy or abraded surface on which to locate and thrive, and are prone to choose some weak point. Whether carried by the air, sputa, lymphatics, or general circulation, cases are recorded of infection through wounds and teeth that have been extracted. The author of the paper quoted cases confirming the same. The state of the health and the assimilation of food, together with tissue nutrition, have more to do with the development of tuberculosis than have locality or climatic conditions. Not only may we have laryngeal tuberculosis as a secondary infection, but we find cases where it is primary. The laryngeal symptoms may be the first to attract attention, and even become far advanced before pulmonary lesions can be detected. This is confirmed by many observers. The bacilli

¹ Taken from the *Medical Record and Register*, Philadelphia.

are recognized in the sputa, there is pain in the larynx, and difficult deglutition. The larynx presents the specific appearance. We find the infiltration, swelling, and ulcers, but still can detect no pulmonary lesion. There must have been some neglected chronic laryngitis, or some solution of these germs. Cases are reported where these local symptoms have yielded to treatment before pulmonary complications were added, and the patients were discharged apparently cured.

Treatment.—Where the general system is not broken down, or the disease advanced to the lungs, sea or mountain-air and high altitudes, especially in pine regions, are of vital importance. Oxygen, pure air, and the absence of germs are here more to be relied on than the thermal or climatic agents. Dr. Browne has ceased to advise the inhalation of medicated steam; but prefers oxidizing agents. Inhalations of vapour from turpentine, oil of eucalyptus, and menthol he has used with success. It is well established that tuberculosis is a blood-poison, as is pyæmia, septicæmia, and the like. Germicides should be used, and benefit will result. He places great confidence in atropine, not only as a sedative, but as a germicide as well. Arsenic often works in the same manner as does mercury in syphilis. So, also, do the salts of calcium, where there are tubercular deposits. The aniline treatment has not been a success, and the gaseous injections are still on trial. Experiments with sulphuretted hydrogen show temporary improvement, with diminution of the amount of sputa expectorated, less pain, and less distress from persistent cough. Still the permanent benefit is doubtful. This treatment needs careful supervision, and should not be trusted to the patients or their friends. The local treatment of tubercular laryngitis gives the best results, especially where systematic treatment is also employed to maintain health and nutrition. Use cocaine, and employ the galvano-cautery or lactic acid to destroy the deposits and induce healthy healing of the parts. Where the infections are local, our success is in proportion to their accessibility. He does not like iodoform or iodol dissolved in ether, as the ether is too much of an irritant, and prefers a brush made with cotton to the spray, in that it coats the surface better, and is pressed into folds which are protected from the spray by the spasm of the larynx. The continued use of the spray he considers dangerous to the cilia of the epithelial cells. Local and systematic sedatives are emphatically called for. Insufflation is not as good as where emulsions are made with acacia, as it is apt to form cakes. Cocaine gives temporary relief, but morphia, belladonna, and balsam are more permanent in their relief of both pain and cough. The surgical measures are to scrape away the deposits with curette or forceps, under cocaine, and apply lactic acid. Do not stab or incise; it may relieve tension and congestion, but is bad in that it gives new foci for infection. For the same reason it is better not to remove glomerulata, unless respiration is seriously interfered with. Tracheotomy, for the purpose of giving rest to the larynx, is useless, and worse. The larynx does not then receive the necessary air and oxygen, and bacilli-infected mucus accumulates. The cold and dry air irritates the lungs and may induce pulmonary complications; besides, the wound may become infected. Intubation of the larynx likewise causes too much irritation and aggravates the trouble, independent of the risk of blocking up the tube; even refrain from removing elongated uvula. He does not approve of the recent suggestion of extirpating diseased portions. Many apparent cures are reported, and he has had such cases himself, but is inclined to doubt their permanence. We can improve the condition of the larynx, stop pain and cough, cause better assimilation of food, and improve nutrition. There result local relief and apparently satisfactory results, but scarcely a cure, as claimed by Schmidt, Bosworth, and others.

Important suggestions.—(1) Early diagnosis and treatment. (2) Do not be carried away with new remedies. (3) Never be too active in destroying tissue; heal instead. (4) It is better to observe facts and be influenced by the experience of many, than by the new ideas of the few.

Dr. Sinclair Coghill, Ventnor, England, advised to treat more to alleviate pain and distress, which tend to shorten life, and obtain as much rest for the parts as possible. Look to body-nutrition. He also quoted cases of primary tubercular laryngitis from infection. The greatest benefit was from iodoform and morphia by careful insufflation. He had seen cases apparently cured. The medium or tissue in which the bacilli thrive was to him more important than the bacilli themselves. We do not see parasites in vigorous tissues; those well nourished are not liable to infection. Do not trust to local treatment alone, but improve digestion and assimilation.

IX.—THERAPEUTICS AND MATERIA MEDICA.

The following papers were contributed to this section:—

Dr. Hugh Hamilton read a paper entitled **The Chemical Philosophy of Remedy.**—He attributed disease to chemical changes either dependent upon defects of nutrition or bacillary invasion. A remedy

might be defined as the use of agents to prevent disease, relieve symptoms, or to repair injury. Antisepticism is suggested by the discovery of the activity of bacteria in producing disease. Changes are readily induced in the chemical composition of the blood, thus forming compounds which may be either physiological or toxic. Clinical experience shows that remedies are those containing efficient oxidizers, active appropriators of hydrogen, or by substitution of radicals succeed in destroying the pernicious products of germs.

Dr. Murrell (London) referred to the general neglect of this branch of medical investigation. Dr. Wormley, and Dr. Stockman, of Edinburgh, were nearly alone in making studies in this field.

Dr. Stockman made an interesting reference to some investigations on the pathology of phthisis made by Dr. Philips, of Edinburgh, on the formation of toxic bodies in phthical cavities. A substance (chemical, and of the nature of a ptomaine) has been detected in the sputa and lungs of a phthical subject, which cause, when injected in mammals or frogs' fever, emaciation, and death. It was also found that the effects of this toxic agent were very largely counteracted by atropine or belladonna.

Dr. Coghill referred to the corroborative fact that the system in a state of disease (tuberculosis) will bear much larger doses of atropine without producing toxic effects than in health.

Dr. J. G. Sinclair Coghill, of Ventnor, Isle of Wight, read a paper on **Chlorate of Potash.** The varying estimation in which chlorate of potash has been held is due to the prevalence of a false idea as to its supplying oxygen to the blood, and also to its injudicious administration. As a salt exceptionally rich in oxygen, it has, without decomposition, the valuable property, *per se*, by its mere presence, of apparently oxygenating or aerating the blood, and so by restoring or exalting this vital character of the circulating fluid, influencing to a corresponding degree the nutrition and functional activity of the various tissues and organs of the body. Beyond this it does not appear to have any specific action in any disease. A remarkable influence upon nutrition of the fetus has been demonstrated by its administration during the period of gestation. Its effects in preventing dyspnoea have been noticed by mountain-climbers; and the author had obtained excellent results in similar condition, coming on in phthisis or chronic bronchitis. It is also a valuable tonic and stimulant in cases of cardiac debility, either organic or functional; also where the blood is impoverished (anæmia or chlorosis). Its value in local conditions of inflammation of mucous membranes is universally recognized in conjunction with arsenic internally. It is very curative in clergyman's sore throat. The ordinary chlorate of potash lozenges are too strong; two grains and a half are sufficient to a trochee to avoid caustic effects.

Dr. H. A. Hare referred to a case of death after taking chlorate of potash in which the kidneys were found swarming with bacilli. Here there certainly was no antiseptic effect. The salt cannot give oxygen to the blood, as it is not decomposed in the body.

Dr. J. Solis Cohen said that he had found this agent most useful in diphtheria.

Dr. Traill Green recommended the substitution of more soluble chlorate of sodium.

Dr. G. E. Magruder found it useful in catarrhal conditions of bowels and their passages.

Dr. Murrell said that the sodium salt has been largely used in England since the publication of Dr. Sainsbury's paper in the *Lancet* calling attention to discs of chlorate of potash.

Dr. Woodbury said that an agent may be expelled from the organism in the form in which it was taken in (*i.e.*, sodium chloride) and yet be available for nutrition and useful as a therapeutic agent. It is probable that remedies act, *per se*, and not on account of peculiar chemical composition (*ex. qd.*, oxalic acid and starch). Chlorate of potash being feebly soluble may be deposited in the tubules of the kidney, and, where possible, might, therefore, be substituted by the soluble sodium salt. As the potassium chlorate is depressing in its effects a very colourable imitation of diphtheria may readily be made from an ordinary case of pharyngitis, and death from asthenia may even be produced.

Drs. Carter and Pollock said that they had used the agent with excellent effect in the condition of catarrh.

Dr. Stewart had used it in bad odour of the breath.

Dr. Charles D. F. Phillips, of London, reported the results of a very valuable original research on **The Action of Certain Drugs on the Circulation and Secretion of the Kidney.** It contained the results of a series of experiments by means of Roy's onkometer upon the action of certain agents (caffeine, strophanthine, digitaline, ulexine, and spartein) upon the kidneys. It was claimed that every true diuretic increases the circulation of blood in the kidney. Digitaline is not a true diuretic, as it increases the secretion of urine only secondarily by increasing the blood pressure and hastening the flow of blood through the kidney.

Dr. Murrell said that the subject of diuretics is one upon which more information is required, and he considered the paper a valuable contribution to the *rationale* of their action. He inquired what advantages the onkometer possesses over Marcy's tympanum.

Dr. Phillips said it was much simpler and more accurate in its results, differing totally in construction from Marcy's.

Dr. Woodbury asked if the proportion of the solid ingredients had been taken into consideration in estimating the diuretic action of the agents mentioned. He regarded water as only incidental to the urinary secretion (for instance, snakes). Urine does not contain any, that of birds is nearly solid. The essential elements are the urea and salts, and their presence and amount must decide diuretic effect. He asked if such chemical determinations had been made in connection with the experiments reported.

Dr. Phillips: Such experiments have been made but are not yet ready for publication.

Dr. Samuel S. Wallian read a paper entitled **The Neglect of New Medicinal Therapeutics**. The author of this paper was sceptical as to the value of drugs in arresting disease or averting death.

Dr. John E. Brackett (Washington) read a paper on **Rhamnus Purshiana, or Cascara Sagrada**. This plant belongs to the Rhamnaceæ and is indigenous and peculiar to the Pacific slope of this country. The herb is larger than other varieties of rhamnus. Its chemistry has been carefully studied within a few years. It belongs to the tonic astringent and resin-bearing class of cathartic agents. In small doses it has a tonic and astringent effect owing to its contained tannic acid. Given in purgative doses, the effects closely resemble those of rhubarb. It is most useful in treating chronic constipation. It should be given for months, regulating the dose according to necessity. Proper attention must also be given to remove any cause for the constipation which may be present. Various solid preparations were described, none of the preparations being official. The dose of fluid extract (best preparation) as a laxative is ℥ v-xv, or as a purgative is ℥ xv-xx. In one case of constipation with bleeding hæmorrhoids, one minim given every hour was sufficient to entirely relieve the condition.

Dr. Murrell said that the drug under discussion is official in the British pharmacopœia, and that they are perfectly familiar with it in England. It is an old remedy, and they used to give it to dogs. He did not consider that it had any special advantages over buckthorn.

Dr. Phillips had obtained very satisfactory results from the use of cascara, and considered it superior to both senna and rhubarb in constipation.

Dr. Ralph Stockman, Edinburgh, Scotland, read a paper on **The Pharmacology of some Bodies Derived from Morphine**.—The experiments were conducted jointly by D. B. Dott, F.R.S.E., and Ralph Stockman, M.D. The relationship between chemical constitution and physiological action must always be a subject of deep interest to pharmacologists. In this short paper they proposed to mention briefly the changes in action resulting from various modifications in the constitution of morphine. How, in 1854, by acting on morphine with methyl iodide, obtained a body which he named hydriodate of ethylmorphia, and which he regarded as a substitution product, the methyl iodide being supposed by him to replace one of the hydrogen atoms in morphine. In the light of our present chemical knowledge, we regard How's body as an addition product, iodide of methyl (CH₃I) being simply tacked on to the morphine molecule. In 1869, Crum Brown and Fraser investigated this body among others, and showed that the original action of morphine is quite lost, and a curare action substituted in its stead. From their nomenclature there can be no doubt that these observers regarded such bodies as addition, and not as substitution compounds. Notwithstanding this, we find that in all text-books and reference-books, these substances are always named and described as if they were substitution and not addition bodies. It is at present generally held that the substitution of methyl for hydrogen in an alkaloid causes the latter to act like curare, no matter what its original action may have been. The addition products, however, are very different in action from the substitution products. The formula of morphine is C₁₇H₁₇NO₃(OH)₂, and it contains, therefore, two molecules of hydroxyl. It is the hydroxyl-hydrogen atoms which are replaced most easily by alcohol radicals. With regard to the action of morphine, it may be divided into two stages—(1) narcosis, succeeded by (2) tetanus. Methylmorphine, C₁₇H₁₈(CH₃)₃NO₃, is morphine in which one H has been replaced by CH₃. Codeine has the same constitution, and this body is simply codeine prepared artificially from morphine. The action is exactly the same as that of codeine derived directly from opium. Ethylmorphine, C₁₇H₁₈(C₂H₅)NO₃, has the same action exactly as methylmorphine. Acetylmorphine, C₁₇H₁₈(C₂H₃O)NO₃, and diacetylmorphine, C₁₇H₁₆(C₂H₃O)₂NO₃, have a similar action to the two preceding bodies. That is, they produce narcosis in very small doses, which is followed by tetanus when larger doses are given. All these

bodies are much more active than morphine, and smaller doses are required. In dogs, however, they produce much greater distress, and much more marked vomiting and diarrhœa. From our examination of their action, we think that none of them are in a position to replace morphine clinically.

Dr. Hull inquired if the author could give any reason why acetylmorphine was so much more energetic in its action than the methyl compound.

Dr. Stockman could not tell, but thought that the present investigation, if continued for some years longer, would throw light upon the subject.

Dr. Murrell referred to emetic effect of apomorphine, which is more efficient than apocodeine for this purpose. The recommendation of the British pharmacopœia to prepare the solution extemporaneously is puerile, since the only change is in the colour. He had a solution four years old which is as physiologically active now as ever.

Dr. Stockman said that codeine is usually given in larger doses than morphine, whereas being more poisonous it should be given in smaller doses.

Dr. Brackett said that he was surprised to hear this statement, since he preferred codeine as being more acceptable to the stomach.

Dr. A. L. A. Toboldt read a paper on **Carlsbad Mineral Waters**, advocating their use in depraved nutrition, melancholia, diabetes, obesity, etc.

A paper on **The So-called Antiseptic Action of Calomel when given in Large Doses** was read by Dr. George S. Hall. In an epidemic of dysentery the author had in some desperate cases obtained prompt beneficial results by the exhibition of a few drachm doses of calomel. He explained its effects by its prompt action upon the liver, causing a free flow of bile, relieving hepatic and intestinal congestion, and sweeping out the contents of the bowels. Secondly, he thought that it might, by becoming dissolved in the bile, as described by Headland, exert an antiseptic effect upon the contents of the intestinal tube.

The discussion took a direction toward the relative value of large and small doses of calomel, and was participated in by Drs. Upshur and Gnezda, of Berlin; Dunlap, Ramsey, Trall, Green.

The Chemistry and Pharmacology of the Nitrites and of Nitro-Glycerine, by GEORGE ARMSTRONG ATKINSON, M.B.C.M., was presented, and in the absence of the author was read by Dr. RALPH STOCKMAN, of Edinburgh. The action of the salts of nitrous acid resembles closely those of the acid which is the essential basis of this group of medicinal agents. Nitrous acid is remarkably unstable; in watery solution of 3000 it may be used for a day or two for experimentation, but it has no advantage over a solution of nitrite of sodium, which possesses identical effects in so far as an acid can be considered identical with one of its salts. Our knowledge of the action of the nitrite group has been chiefly derived from a study of the effects produced by nitrite of amyl. Since here the base (amyl) has a decided action of its own, it is necessary to select a salt in which the base in its combination possesses no well-marked physiological activity. The resemblance between the action of sodium nitrate and amyl nitrate has been pointed out by Gamgee, Lauder Brunton, Hay, Leech, and others. Barth described its highly poisonous qualities. Binz showed that it caused death from general paralysis, especially of the muscular system, no convulsions preceding the fatal issue. Reichert considered it identical in its toxic effects with potassium nitrite. Its effects may be summed up as a paralyzer of muscular tissue, non-striated muscle being affected less quickly than striated. The brain-centres are also affected. The blood becomes of a chocolate colour in mammals (methæmoglobin), respirations are slowed, and temperature slightly lowered. Death occurs in frogs from cessation of respiration; after the heart has stopped its movements it is found in full diastole and quite inexcitable. *Post-mortem* rigidity comes on early. In rabbits, three grains were a fatal dose in one three pounds in weight. The same appearances were found *post-mortem*. In man, small doses (eight grains) produced great tendency to faintness and considerable acceleration of pulse, with decided lowering of arterial tension. Paralysis of respiration is due to the effect of the nitrite on the muscular system chiefly, but also in part to the effect on the medullary centre. Small doses slightly increase the flow of urine; large always diminish it. Urea and uric acid are almost unaffected. Sugar appears in the urine of rabbits after some hours, if the animal be kept very decidedly under the influence of the drug; but rapidly disappears if the administration of the drug be stopped. The nitrite is largely destroyed in the system, being partly, however, excreted as nitrate, partly, probably, as urea; a portion of it is excreted as nitrite. The pharmacology of the other nitrite is briefly dismissed. Nitrite of potassium, nitrite of ethyl, nitrite of amyl act in very similar manner to the sodium salt. Nitro-glycerine acts partly as a nitrite, and partly per

se. In small doses it exerts the nitrite effect as a paralyzer; in large doses it produces convulsions.

Dr. Murrell, of London, England, referred to his discovery of the usefulness of nitrite of amyl in the condition of angina pectoris, and he always advised patients to carry the medicine in a small bottle. The pearls he considered too expensive for use. The tabellæ (Ch.B.) of nitro-glycerine, made with chocolate, he considered dangerous, from their resemblance to confections. He has used nitro-glycerine in one per cent. solution (dose \mathbb{M} v.—xv.) in cases of neuralgia of the fifth nerve, surgical shock, asthma (spasmodic and cardiac), and reflex neuroses. He preferred this in epilepsy to the nitrite of sodium, which had been recommended by Dr. Law. In angina, patients can take fifteen minims when they feel the attack coming on; such patients should carry a small bottle with them for immediate use when they feel the attack coming on, otherwise they might perish before the agent could be obtained. He gave an amusing instance of the difficulty of obtaining nitro-glycerine in England at present.

Dr. Upshur, of Richmond, Va., reported a case in which the inhalation of nitrite of amyl, in a patient suffering with heart-failure and puerperal septicæmia, undoubtedly saved life by cautiously continuing the remedy, whenever there was failure of the pulse, for about forty-eight hours, when it was withdrawn and diffusible stimulants substituted.

Dr. Wade, of Holly, Mich., prefers a ten per cent. alcoholic solution of the amyl nitrite, which he uses by inhalation. He regards it as the best form of cardiac stimulant in sudden emergencies.

Dr. Phillips, of London, England, had experienced headache, dizziness, and faintness after taking five minims of a one per cent. solution of nitro-glycerine hypodermatically. He had found the tabellæ (each \mathbb{M} j. of a one per cent. solution) useful in angina pectoris. Patients usually will not tolerate more than three or four of these, but some will require twenty-five or thirty. The effect of sodium nitrite is more prolonged than that of ethereal nitrates, and for this reason he prefers to give it in dyspnoea attending bronchitis.

Dr. Brackett, of Washington, D.C., reported a case of successful treatment of an epileptic by the use of amyl nitrite by inhalation.

Dr. Wade, of Holly, Mich., recommended nitro-glycerine in cases of threatened local asphyxia of brain from embolism or thrombosis; he had had good results.

Dr. Phillips, in answer to a question, said that he would regard fifteen minims of solution of nitro-glycerine, hypodermatically given, as a dangerous dose.

Dr. Murrell thought that there was no advantage to be derived from its hypodermic use, since it acts so quickly when swallowed.

The next paper was read in German, **On the Poison of the Cobra**, by Dr. Julius Gnezda, of Berlin. The substance from which the experiments were made was brought from India by Dr. Robert Koch. It was obtained by making the cobras strike some shells covered with sheepskin. The poison was afterwards dried. It is soluble in water, but not in alcohol or ether; its activity is lost by boiling. It is uniformly poisonous to higher animals. The European hedgehog and the ordinary swine of this country are popularly believed to enjoy an immunity, but this is explained by mechanical obstacles to absorption in these cases. The poison is contained in an albuminous fluid, but its chemical construction is not as yet settled. It is poisonous when applied to mucous surfaces, without causing blisters. The effect is very marked when the poison is injected into the circulation. The blood-pressure is at first increased, the blood-corpuscles are changed in their shape, and the spectrum of the blood is characteristic. It was found that death did not occur at once, but after about half an hour, and as the result of failure of respiration, so that the Indian Government was induced to recommend artificial respiration in such cases. At present, no antidote is generally accepted. Since it is not known whether the poison is an alkaloid, a ptomaine, or other body, such a question is at present only a speculation. As it is secreted by salivary glands, it is probably an albuminous body. Permanganate of potash has not been found an efficient antidote.

Dr. Phillips, of London, regarded the paper as an interesting contribution to our knowledge of the characteristics of snake-poison.

Dr. Lewin, of Berlin, could not harmonize the report made of the spectroscopic appearance with the usual characters of the blood-spectrum. The appearance was peculiar, and needed further investigation. With regard to the antidote, it may be acknowledged that there can be no general antidote to counteract the poison after it gets into the system; but if the remedy can be injected *locally* into the wounds, then potassium permanganate and a number of agents having a caustic effect may neutralise or destroy it.

Dr. Woodbury said that in regard to the nature of the poison, Drs. Mitchell and Reichert, of Philadelphia, had conducted a series of experiments which seemed to establish the fact that the snake-poison

is not a single substance, but is probably composed of two, one of which is of the nature of a peptone. In the "Life of Francis Buckland," the English naturalist, the incident is given of Mr. Buckland having been inoculated with a very minute portion of the virus, accidentally, under his finger-nail. He shortly afterwards suffered with intense pain at the back of his head, faintness, and collapse, from which he recovered with difficulty after taking large doses of ammonia and brandy. He attributed his recovery to the antidotal effects of these agents. We may conclude that when a minute amount has been absorbed, ammonia and alcohol are antidotal, but where any considerable amount is received into the circulation the case is hopeless.

Dr. Traill Green said that he had made some experiments with snake-poison, and had been surprised by the quickness of the effects on a rat which had been bitten over the jugular vein. Death was instantaneous where the poison entered the blood directly.

Dr. L. Lewin, of Berlin, read a paper on **The Maximal Doses of Drugs**.—Of the many difficulties which pharmacotherapy has to strive against, the dosage of medicine is by no means the least. Variation in doses arises (1) from the differences (2) between one person and another; (3) between single individuals at different times; (4) between the intensity of the disease in men suffering from the same affection; (5) between diseases in which the same drug is used. (2) From the variability in the activity of the greater part of our remedies. At the same time it is possible and desirable to establish the usual dose of agents which are active in relatively small quantity, and which readily produce toxic effects when the dose is increased. Two groups of preparations fall under this head:—(1) Plants (crude) and plant-products, and their pharmaceutical representatives; and (2) chemical substances such as metalloids, metallic salts, and carbon-compounds. The first group is almost universally inconstant in its effects, and thus far an international agreement as to their maximal doses has not been possible. The remedies of the second group, on the contrary, are nearly uniform, and the doses beyond which they cannot be given without danger can be determined by physiological experiments; but although the basis for such agreement is tolerably broad, yet the statements given in different pharmacopœias in many cases vary greatly. Such variation can be easily explained in the case of the first group, but becomes incomprehensible in the second. From the results of his own observation, and a comparison of the most of the pharmacopœias which give maximal doses, the author had constructed a table of the ordinary maximal doses of many of the drugs belonging to the second group, which he appended to this communication. Such a list should be added to the pharmacopœias of such countries as have no maximal dosage, for the convenience of the practitioner, who thus would be enabled to prescribe such drugs with confidence even if they should not be generally used in his own country. From this Congress he hoped the influence would go out which would make such an international agreement possible.

Dr. F. Woodbury instanced the varying effect from chloral hydrate, which is sometimes taken safely in large doses, and at other times it proves rapidly fatal, even in doses of ten grains. He inquired if this effect could be due to the coincidence of digestion and the change of the chloral into chloroform by the alkaline bile, as Liebig believed.

Dr. Stockman said that the amount of chloroform liberated from ten or fifteen grains of chloral hydrate would be so small as to be trifling. He thought that it was not decomposed, but that it acted as chloral hydrate. A good deal of dissatisfaction has been felt with chloral on account of its depressing action, and other agents, such as hypnone and urethane, have lately been introduced to take its place.

Dr. H. G. Beyer, U.S.N., said that Mayer had explained the action of chloral hydrate as that of trichloroacetic acid; and, in fact all other halogen derivatives of organic compounds produce their effects by the chlorine which they contain, which is said to be set free whenever these compounds are brought into an acid medium. For instance, the cells of the cerebrum are supposed to react slightly acid during intellectual activity, but when trichloroacetate of sodium is injected into the blood, the chemical compound is decomposed, chlorine is set free, and sleep produced, or intellectual torpor, in the same manner as this is done by chlorine hydrate.

Dr. John N. Upshur, of Richmond, Va., read a paper entitled **The Emmenagogue Action of the Manganese Preparations**.—The usefulness of potassium permanganate when used as a deodoriser and disinfectant is based upon its readiness to part with its oxygen. Its mode of action is not clear, but in small doses internally it acts like iron, improves the general nutrition, and causes an increased and easier flow of blood at the menstrual period. The permanganate of potassium and the oxide of manganese are both used, the latter being more acceptable to the stomach than the former. It is given in gelatine-coated pills (gr. j. to ij. after meals), and to get its full effect it must be given before three successive periods. In amenorrhœa, due to an impoverished and cachectic condition of the blood, oxide of manganese,

given in combination with some form of iron, will undoubtedly prove of benefit. It is also useful where the condition is due to defective nervous or vascular supply, when pain is present due to functional disorder; also when *no* obstruction exists, but the endometrium is in a state of chronic congestion, or is affected by inflammation due to obstruction which has been removed; in all cases of vicarious menstruation; in amenorrhœa of plethora, when the menstrual derangement is due to functional and not mechanical or obstructive cause, and especially in membranous dysmenorrhœa.

The following papers were read by title:—

On Collinsonia Canadensis, by John V. Shoemaker, M.D.

Cold as a Remedy in Inflammatory Affections, by Hiram Corson, M.D.

The Therapeutics of Alcohol in Disease, by E. N. Liell, M.D.

On Electrical Stimulation of the Mammalian Heart, by J. A. McWilliam, M.D., of Aberdeen, Scotland.

Dr. Julius Anndeer, of Munich, read a paper on **Resorcin**. The author presented specimens of pure resorcin, crystallized, and in combination with cocoa butter, keratin-coated pills and resorcin soap. Resorcin is powerfully antiseptic. It is not irritating to the skin, and is especially useful in the treatment of keloid and similar new growths. Internally it may be given in the form of keratin-coated pills as recommended by Unna. In diseases of the genito-urinary tract it is very serviceable.

Dr. L. Lewin said that the labours of Dr. Anndeer in connection with resorcin were well-known to all present. There was danger, however, of exalting resorcin at the expense of other members of the group to which it belongs, such as carbolic acid, phenol, thymol, and hydroquinone. Dr. Unna had claimed that resorcin was reducing substance in the laboratory, but whether or not it acts in this way in the human system has by no means been settled. It may even be an oxidizer; no one knows how it acts. It is claimed by the author of the paper that it is not poisonous, but when taken in doses of five or six grams per diem it may produce cerebral and sensory disorders resembling mania. This is certainly a toxic effect. With regard to the keratin-coated pills it is not certain that they will pass through the stomach in order to dissolve in the small intestine, or if they reach the jejunum they might very readily slip through without being dissolved. He had found that in the mouths of dogs the keratin coating would dissolve. Moreover, even if the pills were to pass through the stomach undissolved there is no evidence that they would remain and medicate the desired spot. He did not believe in local antiseptic medication of the intestinal tract. He asked why resorcin was better than thymol or other similar agents—phenol, hydroquinone, etc.?

Dr. Beyer, U.S.N., said that he had made some experiments with resorcin and regarded it as an oxidizing rather than a reducing agent. In mammalian blood it acted as an antiseptic, but did not reduce the oxyhæmoglobin.

Dr. Anndeer repeated the statement that resorcin as ordinarily taken is not poisonous. It is antiseptic and quite unirritating to the skin.

Dr. William Ward read a paper entitled **Vicarious Respiration Superinduced in Certain Diseases by Administration of Oxygen-yielding Compounds through the Alimentary Tract**.

The paper was largely devoted to the physiology of respiration and the possibility of supplementing the functions of the lungs by the administration of agents containing oxygen given per os.

A meeting of the Council was held at the close of the session, and a complimentary vote of thanks was passed, on motion of Dr. Phillips, of London, to the venerable President, Dr. Traill Green, of Easton, Pa., for the dignity and urbanity which he had manifested in presiding over the deliberations of the Section and for the faithful performance of his arduous duties, both before and after the assembling of the Congress, and which contributed materially to its success.

(To be continued.)

The Spirit of the Societies.

GLASGOW OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The second meeting of the Third Session was held in the Faculty Hall, St. Vincent Street, on Wednesday, November 23rd, Dr. ABRAHAM WALLACE, President, in the chair. I. McGregor Robertson, M.D., C.M., and H. St. Clair Gray, M.B., C.M., were duly elected members.

There was a large gathering of the profession generally to hear Mr. SKENE KEITH, of Edinburgh, who read a paper on **The Treatment of Fibroid Tumours of the Uterus by Electricity**.—Mr. Keith referred to the fact of this kind of treatment having already suffered from abuse owing to inexperience of the force dealt with, and stated it to have been Dr. Apostoli's merit to place the method on a scientific basis,

and then indicated the apparatus required, of which a battery, a rheostat, and a collector were the principal. The shock is an induction one, and an efficient rheostat prevented this from being undue in amount or intensity. The abdominal mould of moist clay he found to be best made with salt water; and as a preliminary the vagina should be washed with a solution of perchloride and stuffed with iodoform cotton wool. He then gave details of six cases which are here epitomised.

CASE I.—Menorrhagia. Tumour reaching three inches above pubes. First shock of 200 milleampères; sixth raised to 300 for eight minutes; after twenty-six applications, recovery.

CASE II.—Menorrhagia. Anemic. Ergotine first had fair trial. The tumour in this case rose as high as the umbilicus before the menstrual flux. After seventeen applications of 100 to 200 milleampères, recovery, the tumour being reduced so as to give a uterine measurement of three and a half inches. The recovery in this case, albeit, was followed by a relapse.

CASE III.—A fibroid of fifteen years duration; *post climacteric*; æt. 60. Abdomen and pelvis entirely filled with tumour about twenty pounds weight. The current used was from 100 to 200 milleampères. After the fifth application the tumour was so much smaller that it was estimated it had shrunk one third, or lost from six to eight pounds in weight, with corresponding amelioration of other symptoms.

CASE IV.—A patient of Dr. Tanner's. So weak she couldn't walk without assistance. Tumour rose fully one inch above umbilicus. It was doubtful whether hysterectomy would have been successful in such a case. Immediate benefit followed the use of electric current, and after the fifth she walked two miles, and her dress was already too loose. When last heard of she was "very well."

CASE V.—Menorrhagia of some years duration. Small fibroid uterus three and a half inches. Current 200 milleampères, the sound being attached to the negative pole. After seventh application the menorrhagia was still present. Several positive applications were then made, and the patient left well.

CASE VI.—A case from Dr. Bruce: anæmic, but very little pain. Tumour filling abdomen and pelvis. Applications made through needle attached to negative pole on September 11th and October 20th. Two days after the latter date there was no pulsation, and on the 29th she was better. After eighteen applications the tumour was reduced in size two inches, and the patient was able to walk two miles.

In conclusion he summarised the results as consisting in (1) diminished hæmorrhage, (2) diminished size of tumour, and (3) tonic general effects. He had noted that in no case was the excretion of urea diminished. As to the amount of risk attending the operations, he said that he had made 1,350 applications now, in his own and his father's *clientèle*, and had only one accident. He impressed upon his audience, however, the necessity of extreme care, as the least inflammatory condition was a contra indication. In suitable cases he thought it offered relief without the risks and terror of hysterectomy.

Dr. MACINTYRE then gave a **Demonstration of Apparatus used for Electro-Therapeutics**.—He reminded the Society that electricity manifested itself in the three forms—light, heat, and motion; and that it existed in two states—viz., dynamic and static, instancing the means whereby these may be demonstrated. He then passed to a consideration (1) of the physical laws, (2) the modes of mensuration, and (3) the physiological action of the electric current. The clinical purposes were summarised thus—viz.:

To stimulate nervous system	} A current of from twenty to thirty
" " muscular "	
To obtain electrolytic action	} A current of thirty ampères being
" " illumination "	

The positive electrode induced contraction and coagulation, and the negative decomposition of tissues. He remarked *en passant* that a thoroughly satisfactory ampère metre was still a desideratum.

Dr. STIRTON opened the discussion by stating that he certainly was not in a position to criticise, his experience of six cases having been so small. He had always been successful in getting the electrode into the tumours through the os, but had not used any other than the positive pole owing to the instructions given by Dr. Apostoli. The first effect he had observed was that the tumour became movable, and the second that it became hard under the hand. He had used the negative current in a case of amenorrhœa from innervation with success after the first application; but the last condition of the patient was not known. He could confirm Mr. Keith's result generally; but he had had one unfortunate result, the patient operated on having been the subject of cancer of the rectum as well as fibroid tumour of uterus. The positive electrode was used, and nothing but blood issued from the rectum afterwards.

Dr. KNOX had used the method once—unsuccessfully. The patient was æt. 45, suffering from a bleeding fibroid. He had passed a current of only sixty milleampères for five minutes. There had been no obstruction and no difficulty in getting the sound to enter. Death, however,

ensued, and at the autopsy evidence was found of pelvic cellulitis surrounding the uterine neck with pus and metastatic abscesses. He dwelt upon the difficulty of making correct measurements of electrical currents.

Dr. ABRAHAM WALLACE (President) here read an extract from Dr. Apostoli's paper, the purport of which was to enjoin the use of the positive electrode in hæmorrhagic cases and the negative in others.

Dr. OLIPHANT asked what antiseptic precautions had been used in Dr. Knox's case, and received reply that the vagina had been washed out with perchloride solution.

Dr. FLEMING said he was using the method in cases of enlarged prostate.

Dr. W. L. REID found that few men could speak verily of absolute cure in any case. His idea was that the positive pole acts very much as the actual cautery in fibroids and subinvolution, and preferred it.

Dr. MORTON asked if this method had been tried in the case of fibro-plastic or recurrent fibroids; and

Dr. FLEMING replied that he had tried it in such a case, but couldn't say that it had any success.

Mr. KEITH, in replying, thanked the audience, and particularly Dr. Macintyre. He did not find the negative pole any more dangerous than the positive. Albeit it was certainly not advisable to begin with a strong current. He thought 100 milleampères quite sufficient. The punctures should never go deeper than one inch; and he showed a sound covered with gum elastic to within one inch of its extremity. He could not corroborate Dr. Stirton's observation about the hardening of the tumour. In one case he had induced menstruation for *one day only* in an amenorrhœic (twelve months). He regarded the deaths reported as accidental. He could not agree with Dr. Reid at all. Punctures heal at once, even after a dozen times. If there was any caustic action this could not be; sloughs would be frequent, whereas they were rare.

Here Dr. REID referred to Dr. Apostoli's paper, where he refers to "discharges;" and Dr. STIRTON asked whether there was no difference in *kind* of action between the positive and negative? Mr. KEITH replied that Dr. Apostoli referred, in the passage cited, to attempts at making an artificial opening into a tumour, and could not give an explicit answer to Dr. Stirton, but referred to Case II.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—A meeting of the Society was held on November 18th, Dr. RANSOM, F.R.S., presiding.

Dr. HANDFORD read a paper upon **Certain Clinical and Pathological Points in connection with Enteric Fever**, and exhibited numerous drawings of the minute changes in the liver, spleen, stomach, and intestines in this disease.

Dr. HANDFORD also showed tracings of **Muscular Tremors** and a photograph of **Muscular Wasting**, probably due to peripheral neuritis, in enteric fever.

Dr. MARSHALL brought forward the following cases:—Two sisters affected by so-called **Congenital Dislocation of the Hip-joint**. A third girl in the same family had the right hip-joint at fault in a like manner. Of three other members of the same family two died before walking, and the deformity was not therefore noticed, if it existed; and the third, a boy, showed no signs of the trouble at three years of age, when he died.—**Salivary Calculus from a Lady**, 54 years of age (for Mr. Wright).—A piece of **Hazel-nut removed from the Trachea** after death, which had been swallowed nine weeks before admission into the Children's Hospital. Tracheotomy was done unsuccessfully for the purpose of removing the foreign body. The point of impaction was at the bifurcation of the trachea. The left lung was collapsed.

Mr. ANDERSON showed the following specimens:—**Extensive Rupture of the Liver** caused by the passage of a cart wheel over the body of a child seven years old. The rupture was situated at the junction of the right and left lobes, and was so extensive as to almost divide the organ into two parts. The child lived eleven hours, and died from hæmorrhage into the peritoneal cavity. There was not the least evidence of injury externally.—**Dislocation of the Cervical Spine without Fracture**. The specimen was taken from the body of a middle-aged man who had fallen headlong down a flight of steps. He was brought to the hospital some hours after the accident, and only lived a minute or two after his admission. The fourth cervical vertebra was dislocated forwards on to the fifth. The dislocation was bilateral, and the displacement slight. The anterior common ligament remained intact. The cord appeared to have been stretched, but was otherwise uninjured, as were also the membranes round it. There was no fracture.

Mr. PRYER showed (for Dr. Elder) a **Uterine Myomata** removed successfully from a woman, æt. 27 years. It was of very rapid growth, and by its pressure symptoms had quite unfitted patient for getting about. Its weight was ten pounds; and the pedicle was secured by Koeberle's serre-nœud.

Mr. PRYER related the following case for Mr. Truman, and showed

the specimen referred to:—Mrs. G., aged twenty-eight. First and only child eight years ago. Dysmenorrhœa since June, 1886. Abscission of cervix; pain relieved for three months only. Present condition: pain three days before, during, and two days after period, which lasts five days; cannot do any work at all for the ten days. Sexual congress most painful. In right lateral fornix is an enlarged and painful ovary. In median line, slightly to left, is a tumour the size of an orange, to be felt also above pubes; movable independently of uterus to some extent; so resistant as to give the impression of a solid growth. Uterine cavity of normal length. Diagnosis alternative between a parovarian cyst and a myoma with long pedicle. Laparotomy on November 9th, 1887. Right ovary contained a small cystic tumour. The larger tumour was a cyst, parovarian, containing fourteen ounces of fluid, growing from the left broad ligament; having crossed to the right side, spread out on its wall over the left ovary. November 18th: patient quite convalescent, and wound healed up.

LIVERPOOL MEDICAL INSTITUTION, November 16th, 1887.—Mr. PUZEY showed the lungs of a young woman, twenty-two years of age, who had recently died in the Northern Hospital from secondary sarcoma of those organs. The patient first came under his care last January, when she was suffering from myxomatous sarcoma recurring in the stump, after amputation at the knee-joint for sarcoma of the tibia in December, 1885. At that time (January, 1887) there was a suspicion of deposit in the upper part of the right lung; but to prolong life, and to give the patient a possible chance of recovery, amputation through the upper part of the thigh was performed. She made an excellent recovery, and remained well until September last, when symptoms of pneumonia set in, and soon it was evident that the disease was rapidly extending in the lung. Dyspnoea, effusion into the pleura, obstruction to the return of venous blood from the arm and right side of the head and neck, then distension of the superficial veins of the chest and back, and later on an extension of the symptoms to the other side of the chest marked the rapid progress of the disease, and the patient died on November 7th, after little more than six weeks of serious symptoms. The specimen showed all that was left of the lungs, *i.e.*, a small portion of the base of the right lung, and about two-thirds of the left lung. All the rest was converted into soft myxomatous growth, a great portion of which broke up in removal from the thorax. The other viscera were unaffected, and the stump resulting from the last amputation was perfectly sound and unaffected at the time of the patient's death.

Mr. BRIGGS showed tubes and ovaries infiltrated with granulation tissue removed from a patient æt. twenty-one, who had suffered from continuous pain, sufficiently accounted for by the pathological conditions.

Mr. BRIGGS also showed a dermoid cyst of the ovary, removed nine days previously. The clinical features of the case had been frequent hæmorrhages and great variations in the size of the tumour, which, however, was judged from its position to be ovarian.

Dr. BURTON showed an ovarian cystoma, weighing in recent state thirty lbs., which he had removed on Saturday fortnight. The tumour was firmly adhered in nearly its whole extent, separation from the omentum, abdominal wall and bladder being found necessary. The Fallopian tube was enlarged. No difficulty was experienced during the operation, although the pedicle was very thick; but it was followed by very extreme discharge, which necessitated the use of a drainage tube.

Dr. BURTON also showed a sarcoma of ovary, removed from a patient æt. fifty-one, who had suffered for years from dull, aching pain. On examination, a very firm, solid tumour was felt, which at first gave the impression of a uterine myoma, but proved to be unconnected with the uterus on further examination. The tumour was solid, with the exception of a small cyst (which had ruptured) at the lower part. It was the largest ovarian sarcoma Dr. Burton had seen.

Dr. J. M. HUNT narrated the following case, with the patient and diagrams:—M. M.—, factory girl, came under his care on September 19th, suffering from loss of voice of two and a half years' duration. Begun with hoarseness, rapidly passing into complete aphonia; believed to be due to exposure to cold and dust at her work. Voice had not altered during the past two years, though many remedies had been used. Examination showed three small, pale, warty growths, one springing from anterior commissure, and one from the middle of each vocal cord. Growths were pedunculated. No hyperæmia of vocal cords. Growths were removed in three sittings by Shrötter's tube forceps, and nitrate of silver was subsequently applied on three occasions. Result: restoration of voice perfect. Dr. Hunt said the case was chiefly interesting from the point of view of prognosis. The prognosis in cases of laryngeal tumours depends on—(1) Whether single or multiple. (2) The situation; if on or above the cords, the difficulty of removal renders the prognosis unfavourable. (3) The shape and depth of the larynx. If the epiglottis formed an acute angle with the cricoid cartilage, and the growth were situated in this angle, remo-

val would be proportionately difficult. A deeply-seated larynx is also unfavourable, as rendering operative interference difficult, but removal is easy in such a case as the one before the Society—that of a small woman with a superficial larynx. The cautery is often successfully employed in these difficult cases. (4) Size of the tumour, extremes in either direction being unfavourable; but even in cases which from their size present difficulty, a successful result might be obtained after the use of cocaine. (5) Present or past inflammatory action, with increase in size of the parts, rendered operative interference difficult. With regard to recurrence, some authorities have reflected on the propriety of attempting removal of apparently innocent growths on the ground that removal is likely to be followed by recurrence; but out of sixty-seven cases collected by Mackenzie, only four recurred. The usual estimate is that in about a third of the cases operated on recurrence at least once is met with. The chief cause of recurrence is imperfect removal. The nature of a tumour is, of course, a most important point to arrive at, as to whether malignant or innocent, and there is an impression prevailing that laryngeal growths are particularly liable to take on malignancy, especially if removal be attempted. On this point Dr. Symond collected 842 cases, out of which only two had been recorded as having been at first innocent, and having recurred as cancerous after removal; and out of 3,000 operated cases which he had been able to collect from every source, only six were recorded as taking on malignancy after operation. It is very difficult in early stages to diagnose the malignant nature of a laryngeal growth, and on this point clinical experience is a much safer guide than the examination of a piece of the tumour removed operatively or coughed up by the patient, for in the very early stages a warty growth, which will eventually become epithelioma, often shows no sign of epitheliomatous structure. Dr. Symond, after a very considerable experience, has impressed himself very strongly on this point, and has recorded an interesting case in illustration, in which there was a warty tumour on the vocal cord, which on removal proved to be epitheliomatous in one-third of its structure, and innocent in the rest of its extent. If a piece of the innocent portion of the tumour had been removed and examined microscopically, an erroneous diagnosis would have been made. Fortunately, in many cases the clinical history is very clear. A solitary warty growth occurring in a man over thirty-five, situated on the left side, and attended with aphonia or hoarseness (from absorption and pressure of enlarged glands on the recurrent laryngeal nerve), and in which the parts are much congested, is almost certain to be epitheliomatous, and rapid recurrence after removal will generally confirm the diagnosis. In such a case pain may be absent throughout, and the enlargement of the glands may pass unnoticed from their deep situation. With regard to microscopic examination of a laryngeal tumour, while on the one hand the revelation by the microscope of innocence, is not of much value as to prognosis; on the other, the discovery of malignancy is conclusive. Malignant growths are ten times as common in men as in women, and generally situated on the left side.

Card Specimen.—Dr. DAVIDSON showed two enlarged kidneys with double ureters from a case of emphysema and liver disease.

Dr. HOWIS read a paper on "The Weir Mitchell Treatment." He pointed out that while there are many nervous disorders in which a cure is only to be expected from feeding, fresh air, and exercise, the doctor is often disappointed to find that such treatment either fails to improve the condition of his patient, or even renders it worse than at first. There is evidently a gap to be filled up, and the Weir Mitchell treatment proposes to fill the gap. It is intended to prepare a patient suffering from nervous and muscular exhaustion for the following out of the air and exercise treatment which is to effect a cure. It may be compared to a break in a carriage journey, in order to feed and rest the horse and oil the wheels. The patients to whom the treatment is applicable are generally underfed and weak. They require powerful stimuli to movement, but when under the effect of such stimuli an abundance of muscular effort may be manifested for a very short time, as shown in certain cases of hysterical paralysis. The muscular movements called forth may be violent, almost amounting to a convulsion, but soon cease, owing to defective nervous and muscular power. Cases which usually pass as hysteria may be divided into four classes:—(1) Those in which ailment is altogether imaginary; (2) those in which, with some slight disorder present, imagination plays the most important part; (3) cases of distinct nervous derangement, aggravated by imagination; and (4) genuine cases of functional nervous disorder. These last, properly speaking, are not examples of hysteria at all, and it is in this last class of cases that the Weir Mitchell treatment proves so valuable. Of course, a too prolonged rest in bed may give rise to an imaginary disease, and it must be further noted that the Weir Mitchell treatment is not applicable to the case of a patient who can take abundance of open-air exercise without harm. In order that the treatment may be successful, it is of the utmost importance that the medical attendant shall acquire complete

control over his patient. She must cease for the time to have any will of her own, and be brought under the healthy influence of a hopeful mind. If the patient rebel, the doctor must conquer her—not by any harshness, or any forcing of her inclinations; but by kindness and firmness, and by showing her that he is completely convinced that by following his treatment she will recover. She should be told that she will get well, but only by taking abundance of food and exercise, and that the treatment enforced is merely to enable her to do this. Patients often rebel against the treatment so strongly that there is a danger of the doctor's losing his beneficial influence, but he must endeavour to separate himself from the treatment. The Weir Mitchell treatment consists in (1) rest in bed, (2) complete seclusion, (3) moral control, (4) over-feeding, and (5) massage, with perhaps (6) electricity as an adjunct. There had been a general impression that rest in bed tended to impair the appetite, and that was so in many cases; but Gull had found that in certain nerve cases the appetite was evidently improved by rest in bed. He employed rest and feeding without massage. There is a class of patients who suffer from nervous exhaustion, whose friends, seeing that they are easily affected by trifles, conclude that there is very little the matter with them; and these patients, tortured under exertion by the sting of imputed maligning, become worse and worse, and gradually drift into the condition of chronic invalids, until freed by their indisposition to take the rest which they require. After this rest has done its work, medical advice is again sought, and the open-air exercise ordered, and not previously feasible, seems now to effect a cure; for there is a period when the nervous exhaustion having been recovered from, muscular weakness alone remains, and this is relieved by exercise. Nerve tissue is much more easily exhausted than muscular, and as was pointed out by the president of the Medical Society, London, in his address to the Society, this is the reason why voluntary movements are so much more fatiguing than involuntary, as instanced by the heart compared with voluntary muscles, and another example of the same thing is the greater readiness with which fatigue is experienced by recruits at drill than by those who have acquired practice, and in whom the muscular movements brought into play are more or less involuntary.

Seclusion is necessary for two reasons—first, for the sake of quiet, as in these patients the sense of hearing is generally abnormally acute, and often painfully so; and secondly, in order to establish that moral control which is so essential. It is of no use attempting to trust these patients at their own home, but removal need not be to a great distance. It is a common observation how a person's appetite often improves when taking a meal away from home, even if the change is only to the next street or a few doors off. A great object in the treatment is to make the patient experience a continuous chain of agreeable sensations and the avoidance of nervous agitation. Great care should therefore be exercised in the choice of a nurse. If possible, one should be selected who is healthy, fairly strong, amiable, sympathetic, and yet capable of exercising firmness. Anything like fussiness in a nurse is to be condemned, but she should be able to anticipate the wants of the patient before they are expressed. The health of the nurse should be attended to, and she should absent herself from the sick room for a period every day, and take exercise in the open-air. The nurse should be such as to ensure inflexible rule with pleasant environment for the patient, for this is the essence of the Weir Mitchell treatment. A very full diet is required in order to store up material for future use. The appetite of patients undergoing the treatment increases in a very marked manner. Four healthy students who were subjected to the treatment consumed considerably more food and excreted more urea than when taking active exercise. Massage has been found useful in cases of obstinate neuralgia or myalgia, gastric catarrh, various forms of dyspepsia, in chronic joint diseases, and in chronic oedema of the leg. It consists in pinching, rubbing, rolling, and striking the muscles, and moving the joints freely, and should occupy an hour twice a day midway between meals. The treatment may extend over six or eight weeks, and then if the patient be strong enough she should be encouraged to take gradually-increasing open-air exercise, and walking, boating, driving, etc., should take the place of any social or literary avocation she may previously have been engaged in.—Mr. GEORGE WALKER said that massage was only another name for shampooing, which had long been recognized as useful in certain cases.—Dr. DICKENSON considered that the system had great merits, but was rather liable to degenerate into a fad. He referred to the fact that the experiment had been made of training some of the young women at the School for the Blind as masseuses. For this occupation their blindness did not unfit them, as it did for so many other occupations. Indeed, it had been a matter of observation that blind people were far more apt at learning it than sighted people.—Dr. BUOR doubted if nervous exhaustion was proved in these cases. The patients were mostly those who had never done a day's work. Isolation was required, not for the sake of avoiding efforts at hearing, as described by Dr. Henri, but in order to establish control over the patient. There

was a good deal of implied mystery as to the action of massage, but there need be none at all. The muscles should contain about one quarter of the blood of the body. The normal excretion of urea was about $\frac{1}{1000}$ of the body weight. Patients undergoing the Weir Mitchell excreted $\frac{1}{1000}$ of the body weight of urea, showing that their food is assimilated. Dr. Barr narrated the case of a hysterical patient who had been asleep for a fortnight, and on whom the Weir Mitchell treatment had been employed with great benefit. Dr. Barr condemned indiscriminate rubbing, and said that exercise should be strongly urged on patients for whom it has been employed.—Dr. CARTER, in correction of a statement made by Dr. Howis, said that Gull's original paper on "Apepsia Hysterica or Anorexia Neurosa" was published in 1868, but he had previously, in 1866, alluded to cases treated with benefit by rest in bed and full diet. Dr. Carter wished to know if the massage were really necessary as a part of the treatment. In several cases he had not been favourably impressed with massage. In one, that of a lady at Formby, it had been employed for a long time without benefit, and a lady living at Wrexham for whom it was ordered simply could not endure it. In those cases where massage could not be borne, Dr. Carter recommended the rest in bed and attention to diet, forming such important parts of the Weir Mitchell treatment.—Dr. DAVIDSON supposed that male hysterical patients (not the subjects of railway accident) would benefit by the treatment.—Dr. NEVINS, in the course of some observations, said that at present there were only two young women at the School for the Blind trained as masseuses. A woman must be strong to be able to undertake massage, and even a strong woman could not exceed three hours a day spent in rubbing.

Medical Miscellanea.

THE subject of our next illustration will be Dr. George Johnson.

Le Petit Medicin, Paris, No. 95, contains a likeness and brief memoir of Dr. Alexander Harkin, of Belfast.

The Apothecaries' Society of London have sent a petition to the Privy Council praying to be heard by Council in the matter of the petition sent in by the Colleges of Physicians and Surgeons, London.

We regret to announce the death of Sir George Burrows, Bart., F.R.S., M.D., Physician in Ordinary to the Queen. He was the eldest son of Mr. George Mann Burrows, and was born in 1801.

The illness of the Crown Prince still continues to excite great interest in medical and lay circles. Sir Morell Mackenzie's opinion on the case has been misrepresented; he still remains master of the situation.

Mr. Jonathan Hutchinson will give an address at the Annual Meeting of the Cardiff Medical Society, January 26th, "On the Modern Treatment of Obstruction of the Bowels."

We are asked to state that the minutes of the recent sitting of the General Medical Council, with the revised standing orders appended, are published by Messrs. Spottiswoode & Co., 54, Gracechurch Street, London, E.C., of whom copies can be obtained. Price 3s. 6d.

The Lettsomian Lectures will be delivered by Reginald Harrison, F.R.C.S., Surgeon to the Royal Infirmary, Liverpool; Lecturer on Clinical Surgery in the Victoria University, on January 2nd, 16th, and 30th, 1888, at 8-30 p.m., "On some points in the Surgery of the Urinary Organs."

Dr. Scanes Spicer has brought out an excellent form for systematically recording observations and results of treatment in affections of the throat and nose, including adjacent associated areas. Mr. H. K. Lewis, Gower-street, is the publisher.

A medical library and reading-room have been started in connection with the British Medical Association, Strand, London. Mr. Ernest Hart has made a good donation of books, as also have Messrs. Cassell and Co., and several medical publishers, and several medical men have presented copies of their works. Mr. Ernest Hart has been appointed hon. librarian. It is expected the premises will be open shortly after the new year.

We regret to state that Dr. Cross has been found guilty of murder, our regret being that he is a member of our profession.

Madame Boucicault, proprietress of the celebrated Bon Marché, Paris, has left ten million francs (£400,000) to the Assistance Publique for the foundation of another hospital in Paris.

Dr. Humphry Broomfield has been appointed Assistant-Physician to the City of Dublin Hospital. Dr. Bromfield is Lecturer on Anatomy in the Carmichael, and a well-known authority on his subject. He is also an able teacher.

L'Union Médicale gives the following receipt for getting rid of gnats, etc.:—Pour a small quantity of a two per cent. carbolic acid solution into a saucer, slip the fingers into the liquid and sprinkle all the bed linen with it, and the edges of the curtain next to the wall. The face and neck of the sleeper may also be sprinkled. No gnats or mosquitos will come near.

A congress of medical men and veterinary surgeons for the study of human and animal tuberculosis will be held in Paris in July, 1888, under the presidency of Prof. Chaveau; Prof. Villemin, vice-president. The questions which will be submitted for discussion are—1. The dangers arising from the use of the flesh or milk of tubercular animals, and the means of their prevention. 2. The aptitude of men and animals to tuberculosis. 3. The channels of propagation of the tubercular poison into the animal economy, and prophylactic measures. 4. The early diagnosis of tubercle in man and animals. Besides these there will come under consideration sundry other questions, e.g., heredity of tuberculosis in man and animals; contagiousness as from man to man, and reciprocally between man and animals; difference of tuberculosis in different animals; the study of the bacilli in various forms of tuberculosis, etc., etc.

In some courts of justice medical witnesses are treated with scant ceremony. Unfortunately the medical witness has no redress, because the advocate on the bench has supreme power, and cannot only silence, but punish—nay, he can even, from the shelter of his position, damage a professional reputation. A recent case reported in the Nottingham daily press illustrates the truth of this statement. Mr. Robert Brown Hogg, of Worksop, had to give evidence on oath before one of the judges in a case in which a man's leg had been broken. Mr. Hogg was evidently conscientious, and on cross-examination he stated his opinion that he did not think the fracture was caused by a kick, as he found no trace of bruises. He would expect to find something in the nature of a bruise where a man was injured by a kick; he was inclined rather to say the fracture was caused by a fall. A medical man in the witness-box has a right to express his opinion, and he must, when he gives his opinion, justify it. This Mr. Hogg did. We are therefore surprised to find that the judge who tried the case set up as a medical expert and sat in judgment upon the medical witness. "It appears," said His Lordship, "that the doctor had come there after he had taken a certain view of the case. He had made a ridiculous proposition in the box as to the cause of the fracture of the leg. He must mark his disapproval of his conduct by disallowing his expenses." Here the judge exceeded his duty. Mr. Hogg was a witness who had no interest either way, as it was a wretched dispute between two colliers. Mr. Hogg did not know the defendant before he saw him in the Police Court; but he did know the prosecutor, whose wife was a patient of his, so that if interests were concerned it would have been to Mr. Hogg's advantage to have taken sides with the prosecutor. The judge, on the evidence, set himself up as a scientific witness, and openly insulted Mr. Hogg besides punishing him. We must express our sympathy with our *compère*: unfortunately this is all we can do. This appears to us a case which should be taken up by the branch of the B.M.A., if Mr. Hogg belongs to one.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "The Provincial Medical Journal," Horton House, Halifax.

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester; or to the London Representative, Mr. E. BELLA, 58, Charing Cross Road, W.C., to whom all communications respecting Advertisements should be addressed.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

LEICESTER AND SMALL-POX.

To the Editor of "The Provincial Medical Journal."

SIR,—As a contribution to the very important subject under discussion in your columns, may I offer a few brief observations? I do this as a medical practitioner of over thirty years' standing, during which time I have for many years held the position of public vaccinator. In my judgment the official statistics having reference to England and Wales, issued by the Registrar-General, demonstrates as plain as the sun at noon-day, not merely that vaccination is utterly inoperative to prevent or mitigate small-pox, but more, that since 1863 that disease has steadily and greatly increased in fatality, corresponding with increased diligence in the performance of vaccination, the unavoidable inference being (seeing that sanitation and medical treatment have made such great advances within the same period) that the operation is directly responsible for that result; and, further, that their official statistics derive full confirmation from my own experience, and I believe that inquiry would on the part of my professional brethren lead to similar conclusions on their part. I have been much impressed with the perusal of Dr. Charles Creighton's new book on "Cow-pox and Syphilis" (Cassell & Co.), which is probably the ablest, as it is the latest contribution of medical science to this much debated question.

Yours truly,

December 6th, 1887.

AN OLD MEDICAL PRACTITIONER.

 We would refer our correspondent to Dr. McVail's book, "Vaccination Vindicated."

"THE THROAT AND ITS DISEASES."

To the Editor of "The Provincial Medical Journal."

SIR,—Dr. Scanes Spicer's criticism on my book is on the whole so highly laudatory and the defects which he notices are of such minor importance that I should be indeed churlish were I dissatisfied, nor would I ask permission to contradict him on a matter of fact were it not one that involves, in my judgment, a most important point of practice with regard to intra-laryngeal operations. Dr. Spicer states that "the removal of many growths by snares and probangs as recommended by Mr. Lennox Browne is perfectly impracticable." I think he should have added, "in his own limited experience," or have alluded to the circumstance that I have reported in my book, a large number of cases (including every variety of growth that comes under observation of the specialist) all of which have been treated by those means and are attested by the names of well-known practitioners. He might further have quoted my statement that "since the foundation of the Central London Throat and Ear Hospital in March, 1874, neither I nor any of my colleagues present or past have ever used an unguarded instrument" for the removal of laryngeal neoplasms. My reviewer has also omitted to mention that the guarded instruments of Gibb, George Johnson, Voltolini, Stoerk, Jelenfy, etc., have all been used with success by their inventors, and by many others. I append a short corroborative note from my colleagues, and I am, Sir, yours faithfully.

LENNOX BROWNE.

We, the undersigned, colleagues of Mr. Lennox Browne, at the Central London Throat and Ear Hospital, are in a position to corroborate his statement that unguarded instruments for the removal of laryngeal growths have not been used at the Hospital during the period of our connection with it, as designated against our signatures. We further affirm that the same rule obtains in our own practice at this Institution.

ARTHUR W. ORWIN, 9 years.

THE HEALTH OF WORKING MEN.

To the Editor of "The Provincial Medical Journal."

DEAR SIR,—The enclosed letter was received by me recently. It bears evidence of being written by a person with little early education, but with considerable power of thoughtful expression, as well as practical knowledge. The subject is one of pathetic interest to many workmen, and to all right-minded employers of labour. I should be glad if you will find room for it in your columns, printing it as written, merely suppressing name and address of writer.—Yours very truly,

Southport,

December 12th, 1887.

EDWARD DAY McNICOLL.

Stockport, November 22nd, 1887.

To Dr. McNicoll, F.R.C.S.

DEAR SIR,—Having read with interest your able article, entitled "Health saving in the industrial world," allow me to state that your suggestions appear to be feasible, and if carried out practically, would no doubt prove most beneficial.

But, Sir, it would be superfluous on my part to remind you that the corporal system may become so impaired to such an extent, as to render recuperation impossible. Such being the case, permit me to call your attention to what seems to be some of the primary causes that produce this sad result. I shall briefly confine my remarks within the limit of my own occupation—viz., the shuttle trade. The following illustration is a specimen of most of the shuttle workshops throughout the manufacturing districts.

In my present situation there are about twenty men engaged, who have to pass their time in a workshop comparatively small, and is very imperfectly ventilated. Not only so, there is a constant effusion of dry wood dust continually floating in the building. The wood used is chiefly of foreign import, some kinds are evidently injurious to the health, and causes inflammation in the eyes, so that they become swollen, and burn with intensity after one retires to rest. The wood that operates so are commonly known by the names of Membrella and West Indian boxwood. And from the months of October to February, twenty gaslights are used. These lights, together with the men's lungs, must inevitably consume in a very short time what oxygen is to be found in the building. The result is that most of the men are constantly troubled with headache, pains in the chest, and loss of appetite. It is imperative that shuttle wood should be thoroughly seasoned, and for that purpose about forty feet of steam pipes, three inch diameter, are arranged in a serpentine form in the centre of several workshops. The consequence is that the air becomes roasted, and deprived of its natural moisture.

Any intelligent person will see at once that it must be utterly impossible for human beings to secure "health, strength, and contentment" while labouring under such unfavourable conditions, for it would be just as reasonable to expect a stoker to raise a high pressure of steam in a boiler, from bad fuel, as for an employer to look for a maximum of labour from his hands, when they are deprived of the essential fuel necessary for the purpose—viz., fresh air.

It is a pleasure to know that there are a few employers of labour who study the well-being of their hands. Such employers are often rewarded by seeing a greater quantity of well-finished work executed in a shorter space of time than otherwise would have been. The reason of this is obvious, it is simply the result of observing the old proverb (though modified) which says, "That the righteous man hath mercy on his (beast) men, by granting them that which the God of nature intended for everyone to enjoy freely—viz., fresh air."

Many of the above workshops may justly be compared to the historic black-hole of Calcutta, or the hold of a slaveship; yet if one were to lay complaints to factory inspectors, and employers became cognisant of the fact, there are reasons to believe that a feeling of unpleasantness would be the result. Hence it follows as a matter of course, that the parties whose health is at stake, are under a social restraint, neither can they in any way counteract the evil, but are obliged by virtue of their position to remain silent.

Any ordinary student of physiology is conscious of the relation that exists between the heart and lungs and the atmospheric air, the which, if not pure, retards nutrition, corrupts the blood, and often proves fatal, "for the blood is the life." This fountain of the corporal system should by all means be kept as pure as possible. This, sir, in my humble opinion, appears to be the very first question that ought to arrest the attention of economists. First of all, let this indispensable and fundamental blessing, fresh air, be secured. Then, and only then, will a solid foundation be laid whereon to build up grit and fibre, both physical and mental, among our artisan classes, that will enable them to compete with all foreign countries.

Perhaps it would be well if some sort of chemical or optical instru-

ment could be constructed, and placed in every workshop, that would indicate the amount of foul air in such places, so that both employers and workmen may be instructed demonstratively on the subject, inasmuch as the great majority of them are totally ignorant on this most vital and important question.

These suggestions may not be feasible, but at all events it is to be hoped that someone, abler than myself, will shortly devise a final and practical remedy for the evil in question.

Professor Huxley recently remarked, that "experience and observation should form the basis of all human knowledge." Allow me to state that I, together with several others, have been labouring on these grounds to the best of our ability for over a quarter of a century, but have accomplished comparatively nothing. Knowledge on the subject is set at naught when it proceeds from the artisan classes—generally. It will require men of status and position to exercise their influence in the matter, or otherwise it is to be feared that this evil will continue to exist as usual.

The whole substance and burden of my plea may be summed up in the following sentence:—"That all workshops throughout the kingdom be limewashed periodically, and properly ventilated."

Possibly I may have laid my complaints in the wrong quarter, if so, I trust you will pardon me, but it was your welcome article that moved me to communicate to you for whenever any gentleman of your profession deals with the question at issue, it will be sure to meet with a warm response from those who hunger after health as the one thing needful, at least as far as this life is concerned.

In conclusion, I desire to thank you for your noble and humane effort, in attempting to solve this most important problem—viz., "Health saving in the industrial world."

SANITATION IN EGYPT.

To the Editor of "The Provincial Medical Journal."

SIR,—If a man thinks he sees in a branch of his own profession things which should be heeded and reformed, if there are insecurities in the foundations, or even cracks in the window panes; still more, if there is faithlessness or cowardice in any of her members, he is a friend if he speaks out. If he says nothing falsely, and nothing maliciously, he has done well; but if he is counted an enemy because he tells the truth, and if all the effort is to hush up the unwelcome facts, and delude both the world outside and the world inside, with the belief that all is well—that is, the acme of a diplomacy which is only a polite term for duplicity or dishonesty.

If I had shewn malignity in my writing I should certainly have chosen the *Bosphore* as my medium of publication, and no doubt it would have been very glad to have been so used. As it is, however, I never wrote anything for the *Bosphore*, nor have I ever caused anything to be written for that journal, my publications have been in English and American medical journals, a thing which should be observed for my *bona-fides*. Greene Pasha seems to think that my *bona-fides* can only be substantiated by my writing privately to him. Now, Mr. Editor, you can judge for yourself how Greene Pasha has treated my private communications to him. It is not very encouraging is it?

The *Bosphore* may be called an "Anglophobe" paper if you please, but it has published many disagreeable truths that were calculated to correct British wrong doing. Instead of that, however, it would seem that they only stirred up British ire.—Yours truly,

Cairo, December, 1887.

JAS. GRANT, M.D. (BEY.)

To the Editor of "The Provincial Medical Journal."

SIR,—I shall feel obliged by your publishing the following case and comments in your next issue:—

"Bleeding: a prompt remedy for congestive or inflammatory effusion combined with physical obstruction of natural passages." I adduce the following case as the basis of my argument. Mrs. H—, of K—, being in labour on April 20th, 1856, and attended by Mr. Hollinworth, surgeon, was found to have an arm presentation, and the vagina was so swollen that the cavity was blocked up. Mr. H. had sent for the aid of another surgeon—the late Mr. Bywater, Senr.—who gave it as his opinion that nothing could be done for such a case. He left and said they might send for me if they thought proper. I found the parts as described, with the foetal hand protruding beyond the vulva, and recommended immediate bleeding; twenty-four ounces of blood were taken from her arm at once, and a soothing draught given. We retired for fifteen minutes, and on re-examination I found the whole swelling had subsided, and the arm was partly retracted. The child was then easily turned and delivery followed within ten minutes, and the patient made a successful recovery. The reader may note that the bleeding acted fully in fifteen minutes, the entire swelling being then removed. Reasoning from analogy I do not see why the same powerful

remedy may not employed to remove effusion in other passages arising from tumours, etc., that have set up inflammatory consequences and so endangered life; surgical operations where reasonably practical will generally be adopted, but in doubtful or very difficult cases, such as the German Crown Prince's, surely such a remedy deserves a fair consideration. The question whether the tumour be malignant or non-malignant is not the only leading question, but another is whether the effusion consequent on irritation can be rapidly absorbed by the powerful effect of bleeding on the action of the absorbents, and whether, in the event of an operation being ultimately resorted to, the after-reactionary effects of such would be moderated rather than increased thereby to the benefit of the patient.—I am, Sir, yours truly,

Pontefract, December, 1887. GEO. P. ATKINSON, M.R.C.S., ETC.

THE
Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VII.]

FEBRUARY 1, 1888.

[No. 74.]

Our Portrait Gallery.

GEORGE JOHNSON, M.D. F.R.S.

FEW members of the profession are better known, or have exercised a wider influence, than the subject of our sketch. George Johnson was born in November, 1818, at Goudhurst, in Kent. He was educated at the Goudhurst Grammar School, and at King's College, London, where he entered as a medical student in 1839. In 1843 he was appointed the first medical tutor at King's College, London. In 1850, when he resigned that office, he was elected an honorary Fellow of the college. In 1857 he was appointed Professor of Materia Medica; and in 1863 he succeeded the late Dr. George Budd as Professor of the Principles and Practice of Medicine. In 1876 he was appointed Professor of Clinical Medicine, with the office of Senior Physician of King's College Hospital. Having resigned these offices in 1886, he was elected by the Council, Emeritus Professor of Clinical Medicine, and Consulting Physician to the hospital. He is a graduate of London M.B., with the Scholarship for Physiology in 1842; M.D. in 1844. In 1862 he was elected a Fellow or Senator of the University of London; and in 1872 a Fellow of the Royal Society. In 1846 he became a Member of the College of Physicians; and in 1850, having been elected a Fellow, he was appointed to give the Gulstonian Lectures. In 1877 he delivered the Lumleian Lectures; and in 1882 the Harveian Oration. He has served in succession as Examiner in Medicine for the College Licence; as a Junior Censor; and lastly, a Senior Censor in 1875-76. In the usual period of two years, from 1884 to 1886, he was President of the Royal Medical and Chirurgical Society. Dr. Johnson has particularly distinguished himself by his researches and publications on diseases of the kidney, and he has thrown a flood of light on the pathological con-

ditions associated with Bright's disease. His methods of detecting albumen and sugar in the urine are generally adopted by the profession; and in the various controversies which have arisen regarding the pathological significance of albumen and sugar, he has ably defended his own views.

We may here mention, *en passant*, his discovery that in testing for sugar, urine, which darkened from the presence of liquor potassæ on the addition of picric acid, assumed a deep port wine colour, almost black; whilst normal urine gives, with picric acid and potash, a dark red colour. Picric acid has played a useful role in urine testing.

Dr. Johnson has recently published a volume of "Medical Lectures and Essays," of which he says in the preface: "In bringing together, and carefully revising, some of my published writings relating to subjects which I have been led to investigate with more than ordinary care and diligence, my main object has been to communicate to the profession my latest and most matured opinions on such interesting and much debated questions as, for instance, 'The Pathology and Treatment of Cholera;' and of the 'Various Forms of Bright's Disease of the Kidneys;' 'The Relation of Membranous Croup and Diphtheria;' 'The Proximate cause of Epileptiform Convulsions,' etc."

A library of medical works cannot be considered complete without some of the writings of Dr. Johnson. We particularly recommend his treatise on "Diseases of the Kidney" as a book which will be found useful and interesting to the general practitioner.

Independent of various articles contributed to the various medical journals, his chief public works have been the following:—"On Diseases of the Kidney," 1852; "Epidemic Diarrhœa and Cholera," 1855; "The Laryngoscope: Directions for its Use, and Practical Illustrations of its Value," 1864; "Notes on Cholera," 1866; "Lectures on Bright's Disease," 1873.

Original Communications.

ON A NEW METHOD OF TREATING SKIN DISEASES LOCALLY.

By H. VALENTINE KNAGGS, M.R.C.S., L.R.C.P.

III.

A NON-IRRITATING EMULSION OF RESIN OR OIL IS THE BEST SUBSTITUTE FOR ANIMAL PLASMA.

WHEN we consider the methods adopted by nature for the purpose of healing wounds and injuries in animal and vegetable structures, we notice a decided similarity between the two kingdoms.

In animals the continued circulation of the blood in the vessels of the body is an essential concomitant of life.¹ The osmotic flow of the sap is equally necessary to the fructification and well-being of all vegetables. The fluid which we term the blood is in many respects akin to the sap circulating in vegetable structures. On exuding, they both, to a greater or less degree, possess the power of coagulation or inspissation. When poured out in this manner such fluids perform precisely similar functions. A further loss of vital constituents is prevented. Injured surfaces are protected, and temporarily covered up in order that healing may take place.

If, further, we enter into the composition of these various fluids, the similarity of the manner in which their component parts are, in the main, built up, will also be noticeable. For instance, when an animal tissue is wounded, a flow of blood usually occurs. This subsequently gives place to a clear liquid or plasma, which consists of blood deprived of its corpuscles, and contains within it in a state of solution the substances which, on exposure to the air, induce coagulation. The plasma, apart from the living body, is composed of, amongst other things, two essential constituents—namely, fibrin, which may be said to form the analogue of the oil or resin of the vegetable kingdom, inasmuch as it is insoluble in water; and serum-albumin, the counterpart of the vegetable albumen or gum, since it is soluble in water. The circulating sap of the vegetable is often composed of ingredients, which, when extracted from the plant, and allowed to harden, are insoluble in water. During the period of growth they are thinned down, and dissolved by the watery fluids, and other constituents derived from the atmosphere and the earth upon which the vitality of the plant is sustained.

The amount of fibrin constituents found in the blood are known to vary in individuals, and in different species of animals. They may be present in greater quantity than usual, or may be almost absent. Considerable variation is compatible with a condition of vigorous health. Pregnancy and certain forms of disease frequently exert a marked influence in increasing or diminishing the proportion of these constituents. In the vegetable kingdom oily and

resinous bodies are likewise found in connection with the sap of living plants. With respect to their formation, a considerable degree of fluctuation manifests itself in different species or genera of plants of even in the same species. Indeed, these bodies may be almost entirely absent, or may preponderate in one part of a plant and not in another. In some instances, such as the coniferæ, the resinous substances are stored up in very considerable quantities. In other varieties the watery fluids, and substances soluble in water, are in excess.

The gum-resin is, so to speak, the ideal type of the plasma of the vegetable. It often exudes in a state of nature from any diseased or weak point in the cortical layers of the plant. Injuries or incisions give rise to a similar flow of sap. This vegetable compound in the matter of its composition exhibits a decided analogy to the blood. We have the resin in the place of the fibrin, and the gum as a substitute for the serum-albumin. It is a curious fact, however, that the generality of natural gum-resins are acrid and irritating. As a consequence, they can only be used for preparing embrocations, or for stimulating indolent sores, and are unsuited to the treatment of inflammatory skin diseases.

When water is added to a gum-resin, the gum becomes dissolved, and serves to suspend the resin in a finely-divided state. A natural emulsion is thus formed. *Mistura ammoniaci* is an instance in point. Where, however, an uncombined resin or oil is added to water, or to mucilage, complete emulsification does not occur. It is consequently necessary to resort to artificial means to effect the combination. The best method to pursue for this purpose consists in amalgamating a gum in the dry and powdered condition with the resin or oil, prior to the addition of the water. By selecting a suitable oil or unirritating resin we can properly emulsify it with a vegetable gum and water, so that the particles are minutely and permanently subdivided, as in the natural emulsion. An emulsified combination of this kind resembles a freshly exuded gum-resin; is perfectly bland and unirritating; and is, to my mind, the best vegetable substitute for the plasma of the blood.

The so-called mineral fat probably approaches more nearly to the type of an unirritating resin than any other. It is not unreasonable to suppose that these fats were originally derived from the terebinthinous and resinous exudations of the primitive coniferæ of the coal period. By a mellowing process of age and mineralisation they were no doubt transformed from their original condition into the paraffin oils from which such fats are extracted. Experience would tend to confirm this. When used to prepare artificial gum-resins, soft mineral fats in practice give far better and more uniform results than other fats when employed in the form of these preparations.

A comparison of the formula of the emulsion basis, referred to in a previous article, with the composition of blood plasma, may serve to illustrate the analogy between the two compounds.

PLASMA.	EMULSION BASIS.
Substances insoluble in water.	
Fibrinogen Fibrinoplastin	} fibrin. Soft paraffine, 1oz.
Substances soluble in water.	
Serum-albumin	Gum acacia, gr. 160
Chlorides, Sulphates, and other salts	Boric acid, gr. 16
Water	Water, 1oz.

¹ Emulsions occur extensively throughout the animal kingdom. Life, in fact, is carried on in great measure by means of their action. Even the blood itself, the very essence of animal existence, is practically an emulsion, in which, it seems to me, the hæmoglobin, and other ingredients contained in the corpuscles, are suspended in a watery serous fluid through the medium of an enveloping layer of fibrin. The component parts of fibrin, fibrinogen, and fibrinoplastin are in their turn suspended in the albuminous serum. Again, *milk*, a typical emulsion of the mechanical type, is the normal nutrient of mammal progeny. Further, were it not for the saponifying action of the pancreatic and biliary secretions, no food of a fatty nature could possibly find its way into the system through the *chyle*.

Wm. W. F. H. H.
George J. H. H.

In many forms of cutaneous disease the natural healing fluids of the body are apt to become temporarily incapable of properly performing their normal functions. They are not equal to the necessary effort required for the purpose of throwing off the complaint. The affected parts are continually exposed to the atmosphere. Troublesome irritation, with tendency to scratching; foetid or irritating secretions; the presence of irritant substances incidental to the pursuit of many occupations, and other causes, are also liable to further impede the curative action of these coagulative exudations.

It must be our part in such cases to assist enfeebled nature by artificially supplementing her healing forces.

OCCLUSION OF COMMON GALL DUCT, AND DIFFICULTIES IN DIAGNOSING CAUSE OF OBSTRUCTION.

BY ANDREW SCOTT MYRTLE, M.D.

THE recollection of Dr. Ord's most interesting address on "Rarer Symptoms produced by Gall-Stones," tempts me to lay before your readers some remarkable cases of the above common affection, in order to show how difficult it is, nay, how impossible in many cases, for even the most experienced in hepatic disorders to arrive at an exact diagnosis as to its cause.

The first symptom of occlusion is pain about neck of gall bladder; this may be a dull ache, and constant, or sudden and severe, spasmodic. Whatever its character, jaundice quickly follows, and this again may be so slight as almost to escape notice, except on most careful examination, when a few patches of the skin of the face may be seen yellowish, with a similar tinging of the conjunctivæ; or it may be so pronounced that the surface of the whole body is deeply bronzed, and the subject has the appearance of a Red Indian. The excreta may offer the same minor and major indications of the presence of bile; in the milder cases the symptoms may disappear as rapidly as they came; but in the more severe forms they are frequently most persistent and recurrent. In these latter I find gall-stones are most generally accepted as affording a ready and reasonable explanation of the symptoms; and it is only after having failed to discover any concretions of a solid or semi-solid nature in the fæces of the great majority of such patients, on the most careful examination by washing and sifting, that I have been led to the conclusion that gall-stones are by no means the usual cause of obstruction of the gall duct, and that in ninety per cent. the duct is closed by inflammation of its mucous membrane, just as the nostrils are thoroughly occluded in nasal catarrh. When we consider how effectually the comparatively wide canal of the nose is completely rendered impervious to the passage of air, when its lining membrane is inflamed, we can all the more readily understand how the bile is prevented passing through its narrow channel when it is like affected. I have stated that at the commencement of each attack pain more or less intense is experienced, but should the stomach contain food, it is also thrown into spasm of the most violent kind, which nothing in the way of stimulants, carminatives, or opiates will allay; nothing short of complete evacuation of its contents will afford relief, and, I may add, *en passant*, the quickest and best way of effecting this is to administer a large dose of common mustard in a tumbler of hot water. Here I may also add that in all cases of jaundice it is my invariable rule

to inspect the excreta at each visit, and the fæces are washed and passed through a hair sieve after every attack of hepatic colic.

CASE 1.—The late Dr. Pagan, of Glasgow, sent Mr. M——, æt. sixty, of marked gouty habit, suffering from severe and persistent jaundice. Dr. Pagan pronounced for gall-stones. M—— was losing flesh rapidly; his attacks of spasms were intense, ushered in by severe rigors, followed by high fever, and an increase of bile in urine; fæces white. This had continued for six weeks before he came to me; when spasms passed off there was no fulness, no tenderness to be felt at right hypochondrium, even on deep pressure. For a fortnight he got worse and weaker, so I sent him to London; there he was seen by one of the most eminent physicians. A few days after his arrival Mr. M—— was so ill as to require almost constant medical attendance day and night; and the consultant wrote me saying the case was one of cancer, and he was sending him home to die. He went home, and an old friend hearing this, called on him and said to him, "You have been given up by your doctors; we have an auld wife in our village who gives a drink that cures jaundice; were I you I'd send for her." She was sent for, administered her drench, and in three hours afterwards Mr. M—— had the worst spasm ever experienced, almost dying; but when it passed he felt better than he had ever done; asked for solid food; took it with relish. Shortly after that he had a large motion, and on examination a single gall-stone the size of a small pigeon's egg was found. He made a rapid recovery, and for years after he came to Harrogate on account of gout, and many a laugh we had at the fallacies of the faculty and the auld wife's drench.

CASE 2.—Admiral K——, æt. fifty-eight, was sent to me by Dr. K——, of London; he had been seen by three other leading physicians, and several provincial. Symptoms: jaundice, anorexia, emaciation, and diarrhœa; stools offensive, clay coloured; urine like porter. A tumour the size and shape of gall-bladder was seen and felt under the hand; this gave the impression of a bag of small marbles; it was slightly movable, and painful. For sixteen months he had frequent and severe attacks of hepatic colic, requiring hypodermic injections of morphia. All agreed the case was one of gall-stones, and ordered him to Harrogate, as he was too weak to think of Carlsbad. On arrival he could manage to crawl from his Bath chair to my study. I put him on the old sulphur water, and strong sulphur baths. He improved daily as regards digestion and strength, but the diarrhœa and jaundice remained, and so did the tumour. In six weeks he had gained 22lbs. in weight, and could walk eight miles a day with comfort; had no return of colic; felt so fit, determined to go to Scotland for shooting. The night before starting he was seized with terrible spasm, relieved by hypodermic injections of morphia. Dr. K—— had written to the effect that he and his *confrères* had agreed that should another severe spasm, endangering life, occur, cholecystomy should be at once performed, and to this he consented. Dr. Lawson Tait came. On examination, he said, I agree with what all your doctors have said: your gall-bladder is full of stones; they can only be removed by an operation; the chances are 1,000 to 1 in favour of gall-stones; still it is just possible it may be something else, so we shall make an exploratory examination first; if gall-stones, we shall remove them; if anything else, you will be no worse than you were before. This was done. Cancer

of pancreas, involving the gall-duct; wound was closed, and in thirty-six hours the patient died from passive hæmorrhage.

CASE 3.—Mrs. H—— was sent to me by a neighbouring physician. In his letter he said, "The case is one of gall-duct, and should you deem an operation necessary for their removal, I wish you to send her home." She had suffered from hepatic colic for some time, but had not been jaundiced. Her tongue was white, flabby; skin dry and dirty; sickness, acidity, flatulence, constipation; urine loaded with urates, scanty; great tenderness over whole epigastrium and right hypochondrium; slightest pressure caused retching and vomiting. I took a different view of this case from my friend, diagnosing gastric duodenal catarrh, involving common gall-duct; treated her accordingly, and in three weeks she went home fairly well. She has had repeated attacks of the same kind since, for which she has been successfully treated at home.

CASE 4.—Mrs. C——, æt. 32, was sent to me by Dr. D., of London, suffering very much from similar symptoms to Case 3, but infinitely worse. Her attacks of colic were so frequent and severe, she always kept a bottle of morphia by her, in order that she might at once apply to it. On arrival she was so exhausted I had to order her to bed. Next morning I found her jaundiced, greatly emaciated, pain over gall-bladder, nausea constant, with thirst; gall-stones had been carefully looked for, but never found. I at once suspected the symptoms arose from the same cause as No. 3 and acted on the same lines, which were mild sulphur water hot, in aperient doses before breakfast, with strong sulphur baths at 100° Fahr. every second day. After the third week I put this patient on the saline chalybeate springs, and in six weeks she left well. This patient had been suffering for a year or more before coming to Harrogate, and she has never required any treatment since "September, 1886."

CASE 5.—Mr. A——, æt. 62, of very gouty habit, after suffering from flying gouty pains was seized with intense pain over the caput cæcum; this was accompanied with great prostration and sickness, pain continued for some days, and on the appearance of gout in the knees left him. Six months after this he was attacked with severe spasms in the common gall duct, with all the usual symptoms of gall-stones; jaundice followed; motions examined; no trace of any concretion. For twelve months the slightest error in diet, exposure to cold, or mental worry brought back the spasms with jaundice. He felt almost certain that he had gall-stones, and went to London, where he was treated by "kneading," as recommended by Dr. George Harley, with great benefit, but without discovery of any biliary concretions. In this case I suspect gout to have been the cause of spasms in both the colon and gall duct.

CASE 6.—Miss J——, æt. fifty, had felt out of sorts for months. When I saw her first she complained of various dyspeptic symptoms and a dull aching pain in her right shoulder; she could not bear the pressure of her clothes round her waist; tongue red, raw, and glazed in centre; bowels confined; motions natural in appearance; urine loaded. Everything I tried proved useless. I called in an eminent consultant, who candidly confessed he could not make the case out at all. Miss J—— went on for weeks much in the same way, getting weaker and weaker, her symptoms continuing to puzzle us both. One morning on my arrival her nurse said, "I want to show you something before you see your patient." She produced a brown rough gall-stone, which she had found in a loose motion passed

after a more severe attack of pain in the right shoulder than usual; the concretion was about the size of a small horse bean, and from its surface evidently solitary; from that date all symptoms quickly vanished, and perfect health restored. The peculiar features here were the absence of pain in the gall-bladder and duct, the free discharge of bile, and the presence of those symptoms we find invariably indicative of inflammation of mucous membrane of upper intestinal tract. I introduce this case in order to show that we may have a gall-stone, or any number of them, and yet find no spasm of duct, no occlusion, and not one of the usual symptoms which are generally present, at all events, during the passage of such a large concretion through the common gall-duct.

(To be continued.)

ON SOME POINTS IN THE PATHOLOGY AND TREATMENT OF LACERATIONS OF THE CERVIX UTERI.

By THOS. MORE MADDEN, M.D., F.R.C.S.E.,

OBSTETRIC PHYSICIAN, MATER MISERICORDIÆ HOSPITAL, DUBLIN; PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN; CONSULTANT NATIONAL LYING-IN HOSPITAL, EX-PRESIDENT OBSTETRIC SECTION ACADEMY OF MEDICINE, IRELAND; VICE-PRESIDENT OBSTETRIC SECTION BRITISH MEDICAL ASSOCIATION; SOMETIME VICE-PRESIDENT BRITISH GYNÆCOLOGICAL SOCIETY; FORMERLY EXAMINER IN OBSTETRICS, QUEEN'S UNIVERSITY, ETC.

ELSEWHERE, and more especially in America, the pathology and treatment of lacerations of the cervix uteri have received an amount of consideration which would appear exaggerated were this to be merely measured by the scanty attention yet generally accorded to this subject by British gynæcologists. Thus five years ago, when I read a paper on "Hystero-Tracheloraphy" before the Dublin Obstetrical Society, the very name of that operation, or the circumstances under which it would be required, had never been previously alluded to in the *Transactions* of the premier British Obstetrical Association, and to the present day this topic receives far less attention in these countries than it is entitled to. Moreover, although Dr. Emmett, in the last edition of his classic work on "Gynæcology," has kindly expressed his approval of my views as to the frequency and importance of the obstetric complications arising from cervical laceration, still neither this point nor the advantages which I believe are obtainable from amputation of the mutilated and hypertrophied cervix over tracheloraphy in certain cases of stellar and extensive bilateral laceration are, I think, sufficiently recognised by either British or American practitioners. It is obvious, that the prevalence of these injuries can in nowise be affected by any racial or climatic differences on the opposite shores of the Atlantic, whilst as regards their treatment, any method of practice found effectual in New York or Boston should, *cæteris paribus*, have similar results in London or Dublin. Hence, I now venture to submit the result of my clinical observation on these and other points connected with this subject to the judgment of other gynæcologists.

In the present communication I shall in the first place, refer to the increasing frequency of cervical laceration in recent practice, and to the causes assignable for this; secondly, I shall point out the various parturient and puerperal troubles which are consequent on these lesions; and, lastly, I shall briefly recapitulate my clinical experience of the treatment of this accident, and more particularly in reference to the utility of amputation of the cervix in cases of extensive bilateral and stellar lacerations. The latter, when met with, as is often the case in a state of

chronic hypertrophic disease, cannot, I believe, be effectually remedied by hystero-tracheloraphy, and if uncured, may result in life-long misery, even when not eventuating in cancer of the cervix. Such cases, I contend, require and may generally be successfully treated by the amputation of the mutilated and diseased cervix uteri.

With regard to the frequency and pathological importance of cervical lacerations generally, my views are entirely in accord with those of Dr. Emmett—namely, that their importance cannot be exaggerated, since at least half the ailments amongst those who have borne children are to be attributed to lacerations of the cervix. Cervical lacerations are unquestionably now more commonly met with than was the case in my earlier experience some ten or twelve years ago. This fact is probably ascribable to the larger proportion of assisted deliveries in recent midwifery practice, and, above all, to the employment of the unnecessarily powerful axis traction forceps now resorted to, in many cases prematurely, or before the sufficient natural dilatation of the os uteri. Be the cause what it may, however, of the increasing frequency of cervical lacerations, as observed in recent gynaecological practice, there can be no question. Thus in my hospital I have of late years noticed that the majority of child-bearing patients who present themselves for uterine examination are found to have sustained some degree of cervical laceration, varying from a mere fissuring of the os to the most extensive stellate laceration of the cervix. Even the former must be regarded as a condition of some immediate pathological importance; whilst the latter lesion is of still greater consequences in its secondary results, and its reparative treatment is often followed by the complete subsidence of chronic pelvic complaints, formerly misinterpreted and ascribed to other morbid conditions or displacements of the uterus.

Before referring to the secondary consequences of cervical lacerations, we may allude to the primary or more immediate effect of these accidents. The effect on subsequent delivery of cicatrices resulting from cervical lacerations is a matter of practical interest, these being of more frequent cause of tedious labours than is commonly supposed. In my own practice I have on several occasions, in instances of rigidity of the os thus produced, been obliged to incise the os before delivery would be accomplished, and at the present time I have a case of complete uterine occlusion, due to this cause, under treatment in my hospital. In this connection it may, perhaps, be of some interest to observe that, although, until recently, completely ignored by successive generations of obstetric practitioners, the frequency of cervical lacerations, as well as their effect in causing difficulty in subsequent parturition from rigidity of the os uteri, may be found explicitly pointed out by writers so far back as the middle of the seventeenth century, when this was described by Mauriceau in his "*Maladies des Femmes Grosses*," and in England by the younger Chamberlen, who, in his translations of Mauriceau's work, refers to the frequency of "unnatural deliveries from a strong cicatrix, which cannot be mollified, caused by a preceding ulcer or a rupture of a former bad labour—so agglutinated, it must be separated with a fit instrument, lest another laceration happen in a new place, and so leave the woman in a worse condition than before."¹ And even a century later we find in Smellie's "*Cases in Midwifery*," "lacerations of the cervix uteri are frequently alluded to as the

cause of rigidity of the os, and, consequently, protracted labour in multiparous patients."²

Cervical laceration is an occasional starting-point of ruptures extending through the upper portion of the vesico-vaginal septum, and more especially of vesico-uterine fistulæ, and in almost every instance of this kind that has come under my observation the cervical laceration and the extension to the vesical septum was consequent on instrumental delivery. Laceration of the cervix uteri, whether from the premature use of the forceps in the first stage of labour, or from precipitate natural delivery, is moreover a subject of considerable obstetric interest as one of the causes of flooding. I have elsewhere drawn attention to cases of *post-partum* hæmorrhage thus occasioned, of which I have now met with many instances. And I may repeat that "there is reason to anticipate that, when the practice recently advocated of applying the forceps before the natural dilatation of the os uteri becomes generally adopted, as seems likely to be the case, the next generation of midwifery practitioners will thenceforth have an ampler opportunity of witnessing this accident than was the case in the practice of their possibly slower, but certainly safer, predecessors in the obstetric art." For although some authorities hold that the duration of labour, rather than the method of delivery, is the chief factor in the causation of fissurings of the os and cervix, it seems quite evident that no natural dilatation, however rapid, can be so liable to occasion rupture of the circular fibre of the os and cervix as its forcible manual extension, in efforts to complete delivery, by version or the forceps. Some years ago I brought cases before the Dublin Obstetrical Society, in which I had been called in consultation, where the cervix had been thus torn through by the abuse of the double-curved midwifery forceps. The same accident have I seen from version, where the hand was forced rather than insinuated into the uterine cavity before the full dilatation of the os, and have also been consulted when similar consequences had followed undue manual violence in the removal of a retained placenta. In many cases of this kind I have traced hæmorrhage after delivery to its source in the injured vessels of a lacerated cervix. Long since this form of hæmorrhage was described by Gooch, although he failed to recognise its true cause, which was then of far less frequent occurrence than at present. For in Gooch's day natural delivery was the general rule, and accoucheurs had not yet been taught that patient reliance on nature's powers, in cases of unobstructed and uncomplicated labour, might be replaced by hasty operative interference and unjustifiably violent mechanical force.

The special liability to cervical injuries under these circumstances is self-evident, and their physical evidences are obvious to the veriest tyro who has the opportunity of examining the tapering, nipple-shaped neck of the sterile uterus, slightly projecting into the vagina, its apex intersected by a small transverse dimple, or marked by a minute circular depression—the os externum, and then contrasting it with a hypertrophied, truncated, fissured, or lacerated cervix. In the latter we find the results of the lesion in question, in the irregularly gaping mouth, semi-concealed by a glairy, or muco-purulent discharge, through which the everted endo-cervical mucous membrane may be seen extruding in so many of our child-bearing patients, and too often the result of the injudicious use of the needlessly powerful axis-traction forceps now in vogue. In a medico-legal

¹"The Diseases of Women with Child and in Childbed." By Francis Mauriceau. Translated and enlarged by Hugh Chamberlen, M.D. p. 197. London: 1672.

²"Cases in Midwifery." By William Smellie, M.D. Vol. iii, p. 64. London: 1752.

aspect, and especially as a proof of previous delivery, cervical laceration is therefore of unquestionable importance, since by no other circumstances can the evidences of this injury be produced. On the other hand, the non-existence of such cicatrices or fissures is no proof of non-delivery, as the fissuring may have been so slight as to heal within the puerperal period, leaving no obvious traces of the injury.

The connection between laceration of the cervix uteri and many of the chronic disorders of women formerly exclusively ascribed to idiopathic sub-acute inflammation of the uterus, and especially to congestion or ulceration of the cervix, has been clearly established. In such cases the lining mucous membrane is forced down through the gaping edges of the rent as soon as the patient rises from the lying-in bed, giving rise to cervical ectropium. This extended membrane is a focus of irritation, spreading upwards and causing endo-cervicitis, the edges of the rent becoming the seat of erosion, or chronic follicular ulceration; the hardened cicatricial tissue around the rent, after some time, assuming a distinctive character and becoming a veritable neoplasm. A more immediate result of bilateral cervical ulceration is sub-involution of the uterus, which, as well as pelvic cellulitis, may in many, if not in most cases, be ascribed to this cause. In the first instance the inflammation, extending upwards from a cervical wound to the body and fundus uteri, effectually arrests the natural process of involution. In the latter it spreads along the ligaments, giving rise to para-metritis and salpingitis, or reaches the ovaries, thus causing ovaritis or para-ovaritis.

As a cause of uterine flexions and displacements cervical lacerations are of considerable pathological interest, for if the resulting cellulitis so affects either of the suspensory ligaments as to cause its thickening and shortening, the uterus will thereby be thrown out of its normal position, and a constant strain and sense of wearing pelvic pain must be occasioned. These symptoms can only be relieved by relaxing that tension, either by restoring the inflamed ligament to its normal condition, which is next to impossible, or, more easily by taking of the dragging uterine weight by a properly adjusted pessary. Hence the benefit experienced from mechanical support in many cases of chronic pelvic pain, which is more often consequent on cervical laceration than from any primary displacement of the uterus. In the majority of instances the direction of the fissure is antro-posterior, and it may extend through both walls of the cervix, or, as is more commonly the case, be limited to its anterior aspect. When thus situated these fissures, if superficial, often occasion very little trouble, and in many such cases they become healed without any special care during convalescence after delivery. But when from the abuse of instruments, or manual dilatation of the os, to expedite delivery, or from the removal of a retained placenta, or from the unusual size of the child, or from any other circumstance the cervix is extensively lacerated, either bilaterally or split into a number of sections by multiple or stellar laceration, then the results of the accident obviously become far more serious, leading as they must to one or the other of the pathological conditions just described. Under these circumstances, as a rule, surgical treatment—viz., either hystero-tracheloraphy or amputation of the cervix will be necessary. The value of the former, and the procedure by which it may be accomplished, are so familiar, that any reference to this operation would here be more than superfluous. My present object is, however, to call attention to the fact, on which I have elsewhere dwelt—namely, that hystero-tracheloraphy is by no means invariably applicable in cases of cervical laceration,

occasionally failing even under apparently favourable circumstances, and that in some instances we may best treat the long train of symptoms consequent on the injuries by the amputation of the lacerated cervix.

This view is not in accordance with Dr. Emmett's opinions; but though none can more fully recognise Dr. Emmett's authority on the subject, which he has made so peculiarly his own, yet I cannot agree with him that amputation of cervix, except for malignant disease, is necessarily malpractice. The removal of the neck of the uterus for so-called hypertrophy or for abnormal elongation, is also deprecated by Dr. Emmett, who, moreover, is equally opposed to the application of the cautery or of caustics to heal a so-called ulceration on surfaces that may possibly be brought into a healthy condition and united by his operation. If in Dr. Emmett's words, this so-called ulceration, or this elongated cervix, should prove to be merely a laceration, the sides of which can be brought together and united so that the integrity of the parts will be as perfect as if the accident had never occurred, then to resort to amputation is malpractice. This proposition is self-evident. But in the little *if* lies the entire question; and highly as I value hystero-tracheloraphy, and successful as I have generally found it in appropriate cases, I must repeat that in certain cases of extensive stellate lacerations of long standing, with considerable loss of substance, and accompanied with chronic inflammatory conditions of the adjacent structures, or cellulitis, as well as with hypertrophy or hyperplasia of the injured cervix, caused by inflammatory exudations, rather than by any development of the normal cervical connective tissue, tracheloraphy is inapplicable and useless. In such a case we can only cure a patient who is otherwise incurable by the amputation of the mutilated and diseased cervix. Moreover, this operation, according to my experience, is fully justifiable in some cases of non-traumatic hyperplasia, and chronic parenchymatous cervicitis, especially in patients who are hereditarily predisposed to malignant disease, as well as in some instances of cancer of the cervix, either as a curative measure in its earliest stages, or to relieve suffering, if not to prolong life, in the latter stage of the same disease. Finally although in most of the cases of laceration in which I have removed the cervix, the patients have so far remained sterile since then; on the other hand there can be no doubt that this operation is nevertheless called for in some cases of sterility, resulting from the mechanical obstacle to impregnation offered by a greatly hypertrophied, elongated, and conical cervix uteri. Within the last five years I have, for the foregoing reasons, amputated the cervix in a considerable number of cases. I may observe—and my friend, Dr. Hugh Kenneday, who assisted me in nearly all my earlier cases in the hospital and in private practice, confirms the statement—that, so far at least, we have had no experience of the disastrous consequences which some writers insist on ascribing to this operation. I must, however, add that in rather more than half of these cases the patients from whom the cervix was ablated have not since borne children.

THE GENERAL PRACTICAL USES OF ELECTRICITY IN MEDICINE AND SURGERY.

By W. E. STEAVENSON, M.D. (CANTAB.), M.R.C.P.,
IN CHARGE OF THE ELECTRICAL DEPARTMENT (LATE CASUALTY PHYSICIAN TO),
ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO THE GROSVENOR HOSPITAL FOR
WOMEN AND CHILDREN.

It is not my intention to write a paper on electricity as a physical force, or to explain its physiological action. These subjects are dealt with at length in many excellent works on physics and physiology, and also form the contents of valuable

introductory chapters to many of our works on electro-therapeutics. The object I have in view is to present in a practical form the uses to which electricity may be applied in medicine and surgery. It is necessary that reference should be made to some general principles of the subject, and to some of the instruments employed, in order that the descriptions given may be intelligible.

All medical men should possess some knowledge of the medical applications of electricity to enable them to form an opinion as to its value and suitability in the treatment of any cases that may come before them, and also for the purpose of drawing conclusions of any value from the reports of electrical examinations. The batteries to be described may be taken as typical of those in use. The number in the market is very considerable, each of them possessing their own peculiar advantage; in none can every advantage be combined. No less than four or five differently constructed batteries are required to carry out the different modes of treatment and uses to which electricity is put as an adjunct and help in the science and practice of medicine. The difficulties connected with the investigation and treatment of disease by electricity are so great and numerous, that its employment falls of necessity to the lot of specialists. It is impossible for medical men in active general practice to give the time, or afford the money, or possess the manual dexterity necessary for carrying out electrical treatment in all its branches, but a general knowledge should be possessed of how it is used, and in what affections its use is advantageous, and a medical man should be in a position to explain intelligibly to his patients the form of electricity he may advise, and the results likely to be obtained from its use.

The electrical department at St. Bartholomew's Hospital has cost, for its batteries and electrical appliances alone, several hundred pounds, and there is a continual and considerable outlay involved in keeping them all in working order. In addition to some such unavoidable outlay, there is the expenditure of valuable time. The public as a rule will not pay sufficiently high fees to medical men to in any way recompense them for the time which would be occupied in electrical treatment, even if the hard work they have to perform would enable them to give it.

The subject of electricity was first reduced to science by a medical man, viz., Dr. Wm. Gilbert, of Colchester, Physician in Ordinary to Queen Elizabeth. He wrote in 1600, "*Tractatus de Magnete*," and to him we owe the word "electricity." He called all bodies that manifest the same attractive powers as amber (*ἡλεκτρον*) when rubbed "electrics." The word electricity was soon afterwards introduced to indicate the power that electrics possess. Dr. Gilbert does not seem to have applied electricity in any way to medicine, but he will always be looked upon as a pioneer in the investigation of one of the greatest forces in nature. Dr. Gilbert is thus immortalised by Dryden²:—

"Gilbert shall live till loadstones cease to draw,
Or British fleets the boundless ocean awe."

The real inventor of the electric telegraph, as we at present use it, was also a medical man—a Mr. Davy who recently died in Australia. It is said that he when House Surgeon to St. Bartholomew's Hospital first transmitted a message by means of a wire from one part of the hospital to another.

¹ A copy of this work is now in the Library of the Royal College of Physicians of London.

² Dryden's "Epistle to Dr. Charleton."

Neither does it seem that Mr. Davy employed electricity in any way in medicine.

It was more than a hundred years after the time of Gilbert that electricity was first extensively used as a curative agent. Jallabert in France, and De Haën in Germany, were among the first to apply the electric frictional machine to medicine in the early part of last century. In this country it chiefly remained in the hands of non-professional men. In 1759 the famous divine, the Rev. John Wesley, collected most of the recorded cases in which electricity had been used, and published them in a treatise entitled "*The Desideratum; or Electricity made Plain and Useful. By a Lover of Mankind and Common Sense.*" Among the first (if not actually the first) treatise published by an English medical man upon the employment of electricity in medicine was written in Latin² by Dr. Robert Steavenson, of Newcastle-on-Tyne, for some years Physician to the Newcastle-on-Tyne Infirmary, and great uncle to the author of this article. Eight years later (1786), than the date of the above mentioned treatise, Galvani made his wonderful discovery of the continuous current, and in 1831 Faraday discovered the secret of induction which has since provided us with the interrupted current.

Duchenne, of Boulogne, was the great apostle of faradism. To him we owe the enunciation of the truth that for curative effects it is necessary that the current should be localised, that is, applied directly to the parts it is wished to influence. Duchenne found that muscle could be more easily excited at certain points, which he called "*points d'élection*." These points were afterwards proved to be the positions where the motor nerve entered the muscle, or for deep muscles where the supplying nerve approached nearest the skin, and could therefore be more easily excited. These positions are now called "the motor points," and are depicted in most of our works on nervous diseases.

Electro-diagnosis.—Until the last ten or twelve years electricity has been employed by medical men in this country chiefly as an aid to diagnosis. The most useful work on electrical diagnosis is written by Dr. Hughes Bennett,³ Assistant Physician to Westminster Hospital. For the carrying out of investigations as to the electrical excitability of muscles two batteries are necessary; a continuous current battery of about twenty to thirty cells, and a faradic or interrupted current battery. The continuous current battery ought to be provided with some arrangement, such as, what is called, a *dial collector*, by which additional cells may be gradually added to and included in, the circuit, and it ought to have a *commutator*, or mechanical arrangement, for reversing the direction of the current. It is also necessary that a *galvanometer* should be employed, either attached to the battery or independent of it, but included in the circuit, by which the current strength we employ can be gauged. It is only by the aid of this instrument that we can be sure that the same current strength has been used to produce the same reactions in muscles which we may wish to compare. We cannot tell this by the number of cells it is found necessary to employ to produce contractions in corresponding muscles of opposite limbs, because the resistance in the respective

¹ This treatise was republished by Messrs. Baillière, Tindall and Cox, London, 1871.

² "*Dissertatio Medica Inauguralis, de Electricitate et Operatione ejus in Morbis Curandis.*" Robertus Steavenson, A.M., Britannus; Edinburgi, mdccclxxviii.

³ "*A Practical Treatise on Electro-Diagnosis.*" H. K. Lewis, London, 1882.

limbs may vary. This is often the case in a diseased limb as compared with a healthy one. No means has yet been devised for measuring the interrupted current; we must therefore compare contractions produced by its agency with those produced on a corresponding muscle in a healthy subject. The operator should always graduate the interrupted current by the strength which will produce a contraction in one of his own muscles. The most useful muscles for this purpose are those composing the ball of the thumb. Experience gained from the frequent habit of making electrical examinations will teach an operator what corresponding current ought to produce a contraction in any particular muscle that has to be tested. The strength of current given by each faradic battery also varies, so that when using an unknown battery it is the more essential that an operator should first test its effects on his own muscles. Every faradic battery should be provided with a *rheostat*, an arrangement for regulating the current either by introducing into, or removing from, the circuit more resistance; or by exposing more or less of the coil of wire to the influence of induction. The best forms of faradic batteries now in use are those in which the inducing current is obtained from one or two galvanic cells. Nearly all faradic batteries possess two coils—a primary and a secondary. In the primary coil the battery current is multiplied and augmented by the number of turns of wire in the coil, each turn of the wire acting inductively on that which is next to it. The secondary current is a purely induced one, and its strength depends upon the amount of the secondary coil which is allowed to cover over and encircle the primary one. For testing the contractile power of muscle, the primary coil is the best as the secondary produces a current of higher tension (or possessing a greater electro-motive force), and is therefore more painful; but the secondary current is the best for testing electro-sensibility.

For the use of both batteries, continuous and interrupted, it is necessary to have *reophores*, or conducting cords from the battery to the patient. And at the ends of the reophores, for the purpose of applying the current to the patient, it is necessary to have instruments of various sizes and shapes called *electrodes*. These different parts and accessories of batteries that I have mentioned are also used, and will again be mentioned in recounting the therapeutical applications of electricity, but they need not again be explained.

The chief use of electricity in diagnosis is to help in distinguishing cerebral from spinal or peripheral lesions. The current from a constant battery always flows from the positive to the negative pole, and is called a descending current. When the polarity of the electrodes is reversed, for the purposes of diagnosis, it is assumed that the current flows in the reverse direction, and is then called an ascending current. The positive pole is called the *anode*, and the negative the *kathode*. In the reactions of healthy muscle to the continuous current a stronger contraction is produced on closing a descending current than on closing an ascending current; or in other words a stronger contraction is produced in a muscle when the electrode applied to it is negative than when it is positive—*i.e.*, a cathodal closure contraction is stronger than an anodal closure contraction. This is expressed by the formula $C.C.C. > A.C.C.$ The reverse of this reaction is called the "reaction of degeneration," and as far as electrical diagnosis is concerned it is the chief point that can be elicited by the use of the continuous current. In some affections the galvanic irritability of nerves and muscles

is increased, but the reactions may be qualitatively normal. The normal polar reactions of nerves occur in the following order:

C.C.C.	Cathodal closure contraction.
A.O.C.	Anodal opening contraction.
A.C.C.	Anodal closing contraction.
C.O.C.	Cathodal opening contraction.

In the human subject where it is impossible to operate on the exposed nerve the A.C.C. and A.O.C. are about the same in force. The chief practical fact worthy to be noted is that *in health* the C.C.C. exceeds the A.C.C., and the A.O.C. the C.O.C.¹ In the early stages of some paralyses the galvanic irritability is very often increased. This is not so marked after the direct division of nerves, as has been recently shown by Mr. Bowlby, in his lectures last year on "Injuries of Nerves," delivered before the Royal College of Surgeons.² When a muscle is made to contract by electricity independently of nerve excitation the contraction is very slow and wavy as compared to a contraction caused by the same stimulus acting through a nerve.

The interrupted current is more useful in electro-diagnosis. When interruptions take place more frequently than ten times in a second a tonic contraction of healthy muscle is produced provided a current is used of sufficient strength. When the motor cells at the origin of the nerves, or the nerves themselves, are impaired or destroyed, then the faradic contractility of the muscles is modified or lost.

For the continuous current a pad should be placed on an indifferent part of the body, and the electrode applied to the muscle, the condition of which it is required to ascertain, should be made alternately negative and positive by means of a commutator and the contractions produced compared. Then the contractions produced on the affected limb should be compared with those produced on the healthy side, or if both limbs are affected a current registering two milliamperes on a galvanometer ought to produce a contraction. The average resistance offered by the human body, under these circumstances, may be taken to be about 1000 ohms. The resistance of individuals varies considerably, chiefly due to the condition of the skin. More cells will be required with one individual to register two milliamperes on a galvanometer than with another. For all practical purposes the resistance of corresponding limbs in the same individual may be taken as equal, although this is not always the case. If a very accurate examination and report is required it is first necessary to ascertain the relative resistances of the two limbs. This can be ascertained by the help of a galvanometer. If twelve cells of a battery applied to a limb will make a galvanometer register two milliamperes, and the same number of cells from the same battery applied to the corresponding limb does not register so much, there is a difference in resistance—the latter limb offering an increased resistance. In examining for faradic contractility it is best to remove the pad from the indifferent part of the body and attach another smaller-surfaced electrode with a handle to the reophore. If the pad is retained on an indifferent part of the body an interrupted current is so diffused, and so many muscles are thrown into a state of contraction, that no reliable diagnostic information can be obtained. Therefore it is best to apply one electrode to the trunk of a nerve and the other to the individual muscles that the branches of that nerve supply. When it is wanted only to influence the skin, in testing the electro-sensibility of a part, one moist

¹ Hughes Bennett.

² *Vide Lancet*, June 4, 1887, p. 1123.

electrode should be placed on an indifferent part of the body, and the other, a dry one, such as a metallic brush, should be applied lightly to the part to be tested, the skin also being allowed to remain dry.

Galvanism.—The same batteries as are used for diagnostic purposes may be employed for the treatment of many affections that can be relieved by galvanism or faradism. In the use of galvanism for treatment two methods are followed—one the “stable,” in which both electrodes are kept perfectly stationary, the current passing evenly between the two points; the other, the “mobile,” in which one electrode, usually the negative one, is moved over the limb or part it is wished to influence. In both cases the skin over which the electrodes are applied should be previously moistened with salt water. The best form of electrodes are carbon or metal discs covered with chamois leather. The old brass tubes for holding sponges are inconvenient, and can be kept clean with difficulty. Verdigris forms inside them, which offers a greatly-increased resistance to the current. In both methods of administering galvanism it is often convenient to have one electrode placed on an indifferent part of the body. The best electrode for this purpose is an oval plate of pliable metal, such as tin, with a layer of amadou, to retain moisture, stitched on to it, and the whole enclosed in a loose cover of washleather, or flannel, having a waterproof back to protect the patient's clothes. When galvanising the arms this plate electrode can be slipped beneath the collar to the back of the neck, and when the legs are treated it can be placed under the lower part of the dorsal spine and the patient allowed to lie upon it. The greatest chemical and thermal action takes place about the negative electrode, and that is why it is usually chosen as the movable one.

What is called “central galvanisation” consists in applying the negative electrode in succession to the chief nervous centres—viz., to the brain, spinal cord, and sympathetic in the neck; the other electrode being placed on the epigastrium, or some other remote part of the body. This method of electrification is generally employed when it is sought to influence the whole nervous system, as in states of great nervous depression, or exhaustion after long illnesses, or in cases of nervous insomnia. Other special affections are treated by galvanism—such as neuralgia—which are often better relieved by applying the positive pole to the painful area. On the other hand sciatica is more successfully treated by the negative pole,¹ and the current used as strong as the patient can bear it—that is, about ten to twelve milliamperes.

Faradism.—Faradism does not produce the physiological changes which are so characteristic of the constant current, and is generally not so useful as a therapeutic agent. Its greatest use is found in certain forms of paralysis. It helps to exercise the muscles, and thus maintain and promote their nutrition during the time that recovery may be taking place at the origin of the disease. In some forms of neuralgia also it is found more effective than galvanism. When it relieves pain in this way it is most likely due to the production of nerve vibrations. When used for the treatment of general conditions of the system it is either employed in the electric bath or in a way which is called “general faradisation.” In this manner of administering the interrupted current one electrode may be placed on an indifferent part of the body, or the feet placed on a metallic

plate, and the whole surface of the body sponged with the other electrode.

Static Electricity.—In the early applications of electricity to medicine static electricity was the only form used because it was the only form known. For many years after the discoveries of Galvani and Faraday static electricity still remained in exclusive possession of the field of electro-therapeutics. In the Guy's Hospital Reports are several lists of cases of chorea, amenorrhœa, hysterical contractions of muscles, etc., etc., which were successfully treated by this method. The cases are reported by Addison,¹ Golding Bird,² and Sir Wm. Gull,³ who at different times had charge of the Electrical Department at Guy's Hospital. The method of application is the same now as it was when Dr. Steavenson, of Newcastle-on Tyne, wrote on medical electricity in 1778, and is fully described in his work.⁴

The number of accessories required, the expense and cumbersome nature of the machines used and the unpleasant shocks employed in some forms of its administration have prevented frictional electricity from ever becoming a fashionable or frequently-employed agent in the treatment of disease. Its use has of late years been revived, especially by Charcôt, of Paris, and no doubt it is the most useful form of electricity in the treatment of some affections, especially those which are hysterical. No electrical department of a hospital would be complete without a room, or a sufficient amount of space devoted to its use. Static electricity in the form of “the positive charge” has been found useful in general debilitated conditions of the system, such as old age, debility during convalescence from acute illnesses, confinement, or excessive lactation, general prostration from anxiety and over-work, many mental states accompanied by a depressed condition of the system, such as some forms of hysteria, menacholia, and nervous insomnia; and I hope to be able to prove its utility in the treatment of spasmodic asthma.⁵ The reverse, that is a charge of negative electricity, has on several occasions induced an attack of the disease.

(To be continued.)

NOTES ON CONTINUITY IN DISEASE.

BY WILLIAM H. PEARSE, M.D. EDIN.,

SENIOR PHYSICIAN TO THE PLYMOUTH PUBLIC DISPENSARY.

WE must seek to coördinate the phenomena of disease with pathological structure, with vito-chemical processes, and with function; but pathological structure is very much a dead stage; function, in its perturbations, is the great study of the physician in practice; whilst vito-chemical process seems to be the medium or basis, both of pathological structure and disturbed function. In viewing vito-chemical changes within the body, we must never forget that the organism correlates with the “modes” of all the “energies” around, in which it exists, and of which it is, indeed, a part; and that the organism, when viewed from the deductive Form of evolution, has involvements and correlations, with and of existences, which may justly be called infinite. Though we may fail in our

efforts to survey the field of biology—indeed, we know that we *must* fail—in its normal rates or processes of evolution or health; and though we must still more fail to analyse and state the rates and processes of disease—though viewing disease always as in continuity of process and rate with health—yet we have reached an elevation from which we perceive that a grand “unity of method” pervades all the sciences, including medicine. It may be of value to state certain inductive, and even deductive truths, in relation to method in medicine:—

First, a generic type pervades the great fever group, from the equator to high latitudes. We all recognise the differences of the three agues, of typhoid and typhus, of remittent and “vomito” or yellow fever, of cholera and remittent fever in Bengal, of herpes and ague, of asthma and ague, just as we recognise the differences of the languages and dialects of Europe. Not the less, we recognise that a grand generic type must pervade these different diseases, just as a generic type pervades those different languages. And this unity of method, applied to such generic type, would cover not only the field of symptoms, but also it would indicate a grand *general* class of vito-chemical processes, as fundamental in all the varieties. To use the analogy of language yet further—we hold that language is still in process of evolution, that the forms of language now prevailing are not fixed, but are changing with, and subject to, mental conditions and outer environment. And we similarly hold that the fevers of different latitudes, though apparently so different in symptoms and aspect, must have a generic type in their profounder nature, and that a nearly allied vito-chemistry must pervade them all.¹

Further, this generic type is not only seen in what we commonly call the “fever” group, but it is often seen that the “inflammatory” group of diseases show the type of the fever group—*e.g.*, we know of epidemic pleurisy, epidemic pneumonia, epidemic dysentery, epidemic cynanche tonsillaris, etc., etc.; and we often see cases which we cannot classify either as lung cases or fever, and we often see fever which we cannot group under any strict definition or name. And further, we see downright fevers follow and arise from chill, or from mere *change* of environment—arising under the same conditions as simple inflammations arise. I have seen two cases of what could not be called other than scarlatina in the course of an epidemic of measles, in an isolated community, when respectively six and eleven weeks at sea. Thus when we take a justly wide view of fevers, of inflammations, or of those “travelling instances,” the border-land cases, which we cannot classify as fever or as inflammation, we are led to look for a generic type of vito-chemical change in the protoplasm, and in its varied differentiations in the organism.

We have, in our constant and necessary dependence on the varied and different organs and functions of the body,

¹The chemist, in studying the phenomena of the inorganic world, is ever being drawn toward wide, general laws. The hope of generalisation is his inspiration. All chemistry and physics tend to open to our minds widely pervading and common laws. The philosophy and method of chemistry, the inspiring revelation of bonds of union and of general truths, are as absolute an existence to the true chemist as are the matters and bodies with which he experiments. And equally to the physiologist and pathologist, the grand vito-chemical laws which dominate, and are one with, the cellular organic evolutions, must have as great or greater place in biological philosophy than have material structural changes and processes, however minute. The cellular physiology and pathology are less ultimate than are the wider truths of dynamic vito-chemistry, and the absolute continuity of inorganic and organic.

in the necessary division of our labour, and in the exigencies of practice, perhaps too much looked on the body as made up of different organs and distinct parts; but we have to remember, from a large biological point of view, that the body is one organ and being, that the fundamental energy and functions of protoplasm pervade all organs and parts of the body. The differentiations of function and structure are minor parts of the greater common Form of energy and matter, becoming life. Thus many different “diseases” which our classification necessarily recognises must have a pervading common Form—*e.g.*, we see individuals, species, and genera of plants and animals, all somewhat different, but yet more grandly allied; the universal laws or Forms of biological energy pervade them all. We see the energy of creation still evolving in certain cell forms or polarities of the male and female individuals. We see this universal Form of fecundity, not only in the phenomena of the continuance of the species, but in the minor circles of the disturbances of growth and process—*viz.*, in disease—*e.g.*, infectivity develops at times in the states of system known as fever, cholera; more markedly so in other cases, as in syphilis, anthrax, etc. Thus a fundamental motion or energy of infectivity is apt to evolve in a great variety of the tissues and processes of the animal body. We, of course, follow Darwin, that fecundity does not belong alone to the sexual organs, but to each ultimate “gemmule” even. Thus, in a very important sense, we have to recognise that the body is one organ, and that general laws are common to, and pervade, many different diseases. This has long been recognised; and further, this great general truth of continuity seems now to be perceived, as pervading all the phenomena of nature. The phenomena of heat and pyrexia, and their variations, when viewed in correlation with the Form of the correlation of the modes of matter, establish the absolute continuity of the inorganic and organic, and place the laws of pyrexia, as phenomena of disease, within the domain of exact vito-chemistry. Assuming this as a deductive law, we are prepared to approach pyrexia—whether in its extremes, as in tetanus and rheumatism, or in its other more moderate developments—by a method which has reached the light in other sciences. Nor are we to be debarred from such hypothetical approaches because the entire revelation of the laws of the continuity of the inorganic and organic does not yet appear. It is no small step in method when we have reached the perception that pyrexia, and many diseases, must be viewed as in continuity with the modes and correlations of universal matter and energy, rather than as so many distinct entities. This larger view of the science of medicine must enlarge and more firmly establish the art of medicine.

We thus perceive that diseases are disturbances of the prevailing harmonious correlations and equilibrium of the vast series of actions involved in life. Life, as seen in the organic, has a period of evolution of coördinate and equal duration with the cosmos itself; life exists in the so-far ultimate energy, and disease can have no less wide correlations. Thus it happens that the smallest changes—often the smallest alterations in the molecular (isomeric or allotropic) states of vital composition and compounds—may disturb those correlated and harmonious modes on which health depends. The changes so induced must obey orderly laws, equally as do all other inorganic chemical changes. Further, it is impossible but that some one great general law must prevail, say in the great fever group. In physics and dynamic chemistry an infinite variety

of facts and phenomena have been brought within the same great laws. As an example of groups of phenomena, which, separated as they are to common observation, yet show, from a wide biological view, a continuity, I may cite the *præ-mortem* evolution of molecular modes of organic radicals, the "poisons" of tetanus, when that disease follows simple wounds; of cholera, in its great varieties of degree, and resulting from mere change of place, or change of season, sudden rains, or shock; of yellow fever, when at periodic intervals it shows in the unacclimatised, from the shock of joy or fear, or from the shock of passing a catheter, etc.; of fever, like to typhoid, showing in new comers in varied climates, when they are subjected to change of environment; of cynanche tonsillaris, when epidemic in young people, when they *change* their environment from the southern tropics to higher west-wind south latitudes; of outbreaks of herpes, when changing latitudes in voyages; of epidemics of mumps, when changing latitudes, after having been many weeks at sea. In the above instances of the evolution of well-marked "different diseases," I think that philosophic method and analogy justifies the hypothesis that the *præ-mortem* changed modes or poisons, which preceded or precipitated all the variety of the "different diseases," must have been of one generic type; that the operation of one law or order grandly pervaded all. As the protoplasm of the body is ever undergoing the most active changes, and as it is ever dying, ever passing into more stable, less vital, organic radicals, I see a continuity of law and order between such *præ-mortem* and the well-known *post-mortem* modes or "poisons." All of us have probably recognised the familiar *post-mortem* odour of the breath in old people in varied illnesses.¹ We recognise generic "types" in the vegetable and animal kingdoms—it is true, not absolute, for nothing seems absolutely fixed to sufficiently wide observation of the times and order of nature, when we view the paleontological series, or when we submit our minds to the method of evolution. These types are a greater part of the Form of any genera than are the differences of species, however highly these latter may be individualised; and so in diseases, and in their vito-chemical evolution and process, we may fairly expect a generic type, be the resultant different diseases ever so clearly marked. The hypothesis of one great type of vito-chemical change, as the mode of protoplasmic deviation in so many different diseases of the fever group, is not only in analogy with chemical and biological methods, but it is further an approximative explanation of the border-land cases, which though we call them "fever," cannot be classed under any specific name, and of that other border-land group, which cannot be classed either as fever or congestion of the lungs.

From a wide biological view, and applying the hypothesis of continuity as a deductive truth, the molecular states of the normal secretions of some animals—such as the salivary secretion of snakes, and the normal poisons of other animals—establish the fact that the appearance of molecular modes of poisons in protoplasm, is a natural and

inevitable law of the great Form of the evolution of life. The hypothesis of continuity will further regard the existence of the vegetable poisons, strychnine, opium, oil of almonds, etc., etc., not as fortuitous, not as teleological, but as the result of conditions nearly related to those which precipitate within the system modes or poisons, which are followed by tetanus, coma, cholera, etc. Nor can one avoid remarking that many of our deviations, both of growth and function, have correlation with the molecular modes of inorganic bodies and of organic radicals. Hardly a growth or a function but which has its continuity in the cosmic evolution, with molecular the modes of mineral or organic bodies—*e.g.*, that opium has correlation with the function, and energy, and modes of cerebral cell-contents, shows an alliance in the series of the fundamental evolution, and that the same mode of molecular energy or motion exists in both. As already remarked, a large proportion of our mental powers, most of the senses and animal passions, many of the functions and even growths, all find in the organic kingdoms, both vegetable and animal, bodies (molecular states of organic compounds) having a very near capacity for correlation or transmutation into such different modes of brain-cell or mind, or of other of the varied functions of the body. Such facts are nothing but the record of the unity of method of the entire evolution. Our therapeutics, therefore, are but the early empirical approaches to a vast law of continuity in evolution—a law of continuity from the inorganic and vegetable to the highest differentiations of the highest animals. Such a law of continuity must embrace vito-chemical action, and involve the varied modes of the correlations of energy. Our therapeutics thus becomes the highest of all scientific studies, being based on the widest laws, and embracing all the manifestations and Forms of matter and energy.

I have cited the example of strychnine as producing tetanus, and that of tetanus following a simple wound. Here, in the latter case, we may hypothetically surmise that the wound has led to a devolution of the highly differentiated vital animal compounds into more stable alkaloids, having molecular powers like to the vegetable evolution, strychnia. Time would coördinate the prevailing organic plasma to the modes of the new devolution or poison, but in the meantime the patient dies of the terrible convulsions of respiratory and cardiac action. Or take the example of cholera, in those instances where the patients are struck down as with a blow, in the earlier stages of some epidemics—the pulse is gone, the heart ceases to beat. How like to the results of some of the cyanogen series! We hypothetically reason that compound-radicals—nearly isomeric or allotropic with the cyanogen series—have evolved out of protoplasm. The compounds of the living body having reached an age or stage of unstable equilibrium, the smallest changes in environment are enough to lead to the devolution of the highly-differentiated normal organic compounds into more stable earlier forms—organic poisons—related to the cyanogen series, and cholera has thus its evolution or autogeny.² There can be no chance or accident in the facts of the existence of strychnine in the vegetable world, and

¹ I remember an old lady of eighty, of tough constitution, but with an old-standing winter cough. I was called in the evening, and found her very low, with hardly power to bring up the phlegm, and her breath had the smell of a corpse. She was a violent teetotaler, and said she would not take any alcohol. I, however, went out, and returned with a bottle of Gilby's best port, and made her drink two wineglassfuls at once. The next morning, the *post-mortem* smell was gone. She scolded me, but confessed that she was better. She lived three years after. It is not unreasonable to think that *præ-mortem* "poisons" were in process of evolution, that actual death was beginning, and that the alcohol arrested the devolution and death.

² "The cyanogen compounds may be considered as derivatives of ammonia." "The cyanogen compounds are remarkable for forming series of polymeric modifications." "Hydrocyanic acid has . . . been obtained by the direct union (without condensation) of nitrogen and acetylene, when a series of electric sparks is passed through a mixture of these gases" ("Roscoe's Elementary Chemistry," p. 349).

"Ammonium cyanite . . . undergoes gradually, at ordinary temperatures, and at once at 100°, a remarkable molecular change, becoming urea" (*Op. cit.*, p. 353).

of its nearly allied isomeric or molecular evolution in protoplasm after wounds. The law of continuity compels us to acknowledge that vegetable and animal protoplasm are of one series, and though they be sometimes so greatly differentiated, they are not the less results of the same continuity of energy. We all acknowledge the allied nature of vegetable and animal tissues in normal growth, and it is *à priori* certain that the deviations of protoplasm and structure in the two kingdoms, will sometimes pass into compounds and courses common to both, natural overlappings or reversions in the great evolution.

Again, taking cholera as an example, the auto-genetic theory explains the sporadic, and the periods of intervals of epidemics. The outbreak is so far explained, by the hypothesis, that the human race, under allied conditions of climate, has necessarily allied, general tendencies to changes in its protoplasm. The milder type of epidemics at their close show that the periodic tendency to change in any race has been pretty much exhausted in the earlier outbreak. Therapeutics also confirms the hypothesis, for few can doubt that the cholera pill of Indian bazaars, and other medicines—opium, alcohol, etc.—have often arrested the full evolution of cholera.

It seems impossible but that we hold the opinion that our present classification of disease—say of fever—is too defined. In nature, what we call the different fevers, however distinctive and specific they may be, in certain instances merge into border-land types; and even some of the usually distinctive inflammations not unfrequently show with the distinct type of fever, and even acquire the motion or energy of infectivity. And this is true, not only when viewing disease as it appears in different latitudes, but also in viewing disease in the same latitude in different epidemics and seasons, and in different individuals. Even already, chemistry presents us with an approximate hypothesis, as coördinate with and explaining such observations on the merging of types of disease. The vegeto-alkaloids, say of opium, have a nearly identical composition; they re-act chemically like ammonia, but their difference of action on the living body varies out of all seeming proportion to their differences of chemical composition. Or again, many essential oils are isomers of turpentine ("Roscoe," *Op. cit.*, p. 396), yet their influence in the living system varies vastly. Thus chemistry presents us with organic compounds nearly isomeric, but with the most marked differences in their correlations with animal function; and yet these marked differences, in other instances, present most delicate gradations in their relation to function. In the present state of our practical observations of disease, and of our knowledge of isomeric and molecular chemistry, it seems legitimate to hold the hypothesis of the continuity of disease with health; and that this continuity is seen in the autogeny or evolution of "poisons," often isomeric, but molecularly different from the prevailing modes of organic plasma. As examples, I have cited the evolution of cholera from a great variety of changes, and tetanus as evolving from the changed modes of organic plasma, following simple wounds.

The molecular condition of bodies is deeply related to their therapeutic powers. Even organic compound-radicals can take the place of mineral elements in bodies. "The carbon atoms, however, not only unite with each other in large numbers, but form groups of great stability, which in organic compounds take the place of the elementary radicals of the mineral kingdom" ("Cooke's New Chemistry," eighth edition, p. 333). The molecular therapeutic

powers of such must correspondingly vary. As an illustration of the great differences in properties which molecular changes effect in isomeric bodies, Cooke says (*Op. cit.*, p. 339): "The aldehydes . . . have very striking and characteristic qualities, and these qualities may be, to a great extent, traced to their peculiar molecular structure. If we only make so small a change as to transfer the oxygen atom from the terminal to one of the central atoms of the carbon nucleus, we obtain a class of compounds which, though isomeric with the aldehydes, have wholly different qualities, and are called ketones." Such facts in the nature of the powers—including therapeutic powers—of molecular constitution in isomeric organic bodies, if further viewed in relation to the vast number and variety of bodies which are formed from isomeric carbon groups, will prepare our minds to expect the evolution of compounds from the tissues and protoplasm of animals; and in so exquisitely balanced, and even infinitely changing processes, ever happening in the organism, it seems almost like an *à priori* truth, that these new compounds shall be at times inharmonious in mode, even to the degree of being fatal "poisons." I can never doubt that at recurrent periods, chill, and various other changes in environment, have led to the evolution of cholera and varied well-defined fevers, just as chill has led to the evolution of cynanche. The varied and wondrous molecular powers and capacities of apparently simple carbon compounds point to a hypothesis co-equal with the phenomena and evolution of cholera, fevers, etc., etc., and the more so when we take a justly wide view of the gradations of fevers, cholera, epidemic pleurisy, epidemic pneumonia, etc., etc. Dr. Thudichum ("Tenth Report to Privy Council, 1867," pp. 154, 155) illustrates the great influence of the "polarity" of atoms on the qualities of compounds, and further says that "there are several turpentine substances distinguishable only by the different influence on the polarised ray of light." Such facts reveal to us the infinitely minute molecular conditions on which the greatest differences in properties depend, and they have great bearing both on the actual changes which precede and mainly precipitate disease, and on the modes of action of our therapeutics.

The hypothesis of cosmic evolution will compel us to bring our therapeutics within the law of continuity. As before remarked, the existence of strychnine in certain vegetable seeds, and the evolution of its hypothetical isomer in our tissues after a wound, must involve the operation of a common law or Form. Further, as we are compelled to apply a pangenetic hypothesis to the evolution of the parts and qualities of plants, so we are led to expect that the qualities and functions of the tissues of an animal are not so greatly localised in differentiated organs, but are rather generally diffused or existent in all the tissues; and thus in a disease like tetanus we should search for its conditions, not wholly in the medulla and its nerves, but also in molecular changes diffused in the cell-contents and "gemmules" of the living protoplasm.

It seems vain at present to attempt to express these complex molecular vital changes and forms by chemical symbols.¹ But it does seem worth our while to indicate

¹ Professor Cayley ("Nature," vol. xii., p. 483; "Report of British Association, Bristol, 1875") establishes from mathematical law "that theoretically, for a body whose formula is $C_{13}H_{28}$, there exist 799 isomeric bodies. It is worthy of remark that the mathematical theory agrees with experiments for the first five bodies, thus affording strong confirmation of the truth of the remainder."

the breadth of the laws which are involved in human deviation or disease, not only for the sake of philosophic "unity of method," but for the sake also of getting on the right method of prophylaxis—*e.g.*, in a case of tetanus which has shown, say, two weeks after a simple wound, we are certain that molecular processes have been happening, according to absolute law and order, during such interval. It cannot be more beyond our reach to arrest such processes than to produce them by wounds or by strychnine. Again, we can never doubt that there is a prestige of unstable equilibrium of the molecular modes of protoplasm which precede cholera outbursts. The final precipitation of the fatal degree or amount of change is often effected by the smallest changes in environment—*e.g.*, chill, emotion, shock, change of place, change of drinking water, etc., etc. We see here the law of continuity, which directs us to prophylaxis, to coördinating the unstable equilibrium of the body with its environment; and such means of coördination must be as delicate in degree, and as absolute in continuity, as are the precipitating conditions. Man has so far read the laws or rates of mechanical motion as to have built up the science of astronomy. He has further read, or is now in process of reading, the method of the correlations of the physical energies. But these studies are elementary stages of those more complex and involved series which obtain in the organic. The deductive Form of continuity assures us that organic existences obey orderly laws.

Whether we contemplate the facts of disease or of therapeutics, the potentialities and continuity of the carbon compounds with both chiefly fill up the view. The unconquered regions of disease are being attacked on one side by the great advances of the higher chemistry of the carbon compounds; and no less are they being attacked on another side by the *experimental* practice of our therapeutics, whilst the mind is left justly expectant and receptive under the great Form or deductive law of Continuity.

NOTE.—Dr. Hodgkinson—quoted by Lockyer, "The Chemistry of the Sun," London, 1887, p. 60—says, "In the case of many compounds of carbon alone we are able to trace them through their entire range of existence. . . . In all cases the complex groups, formed from simpler ones, have related but not identical properties. In other substances this range of conditions of existence passes gradually out of our reach, but the phenomena remain the same in kind. Atomic combination or condensation is probably the cause of what is termed the 'allotropic state' of some forms of matter. It is strikingly in analogy with polymerization, but its investigation is at present out of our reach."

FROM GENERATION TO GENERATION: A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.
F.R.S.L., ETC.

(Continued from page 15.)

Diseases of the Respiratory Organs.—In proceeding to consider the hereditary element in the diseases of the respiratory organs, I shall not content myself by merely stating that certain of these diseases are distinctly hereditary, but taking a broader view of them all, I contend that, for reasons insisted upon over and over again in the foregoing pages, there is a predisposition of tissue inherited by those who suffer from any of them, as, indeed, there is, and must be, in all morbid processes which are not distinctly

acquired. As I have already stated the nature of these predispositions is unknown to us, but of the following fact there can be no doubt—*viz.*, that physiologically, psychologically, and pathologically, also, the textural and functional peculiarities of ancestors and parents are handed down to their descendants by heredity in varying proportions, modifiable by variability and the influence of external circumstances. The law of heredity is inexorable, affecting body and mind in health and disease, so that every record of disease in a parent's life-history is stamped indelibly on the tissues of his child. Let me not, however, be misunderstood; I do not mean that the diseases of the parents are handed down in every case as entities to their children, but that the textural or dynamical peculiarities of parents, whether inherited or acquired, will undoubtedly be reproduced, in varying proportions, and subject to certain modifications, in their children, as, at least, predispositions to the same. This is very mysterious; and although we cannot understand or explain the processes by which such effects are caused, we must, as the result of observation and experience, accept the fact that, as surely as a child resembles his parent or parents in his or their external configuration, so assuredly does the resemblance extend to his internal textures and organs, and even to a predisposition to the same morbid processes from which they may have suffered, and which he has inherited from them.

Pulmonary Phthisis.—Of the diseases of the respiratory organs none, perhaps, is more dire in its effects, or more unquestionably hereditary, than pulmonary phthisis or consumption, which has been known to exist contemporaneously with the sources of our historical information, and to which, according to Hirsch, probably two-sevenths of all deaths are now due. Without entering into a discussion of the various pathological theories which have been broached from time to time as to the real nature of tubercle, I shall content myself by observing that there is a correlation, however imperfectly understood, between the scrofulous and tubercular diatheses, and that while both are markedly hereditary, the tubercular diathesis is met with only in the scrofulous. "How this inherited diathesis," says Ruehle,¹ "is produced, or what is its real nature, are questions beyond our present knowledge; but if the external form of the body, and mental qualities, can be transmitted in families through generations, why should this not be the case also with the conditions which produce a disposition to certain diseases? If in the former case we do not demand that the comparison be made only between children and their parents, but include also the grandchildren and nephews, why should we not observe the same rule in regard to the inheritability of disease? Why do we narrow the question to asking whether the father or the mother is known to have the same disease at the time of conception? Is not a disease often present before it can be recognised? May there not be a disposition sufficient to be transmitted, although it does not manifest itself as a recognisable disease until afterwards?" In reply to such questions as these, I unhesitatingly reply to each of them in the affirmative. For, in the first place, as heredity is a law of our being, and as the material, functional, and dynamical peculiarities of ancestors and parents are transmitted by them to their descendants, it assuredly follows that the conditions which produce a predisposition to any morbid process are also transmissible.

¹ Ziemssen, vol. v.

We are too liable to narrow down the question of hereditary descent as if affecting only the qualities inherited by a child from his parents, whereas it is a matter affecting the evolution of the race. For every living individual has been dependent upon some other or others as far back as the history of man is recorded by the hand of time; for has not every unit of the human family originally sprung from one source? and if we could each trace our pedigrees back into the ages when man first made his appearance upon earth, we should find them all converging in him the primal and earliest father of our race—whose brow first shone with the divineness of humanity. If heredity is a law of our being, it has been so since man first appeared on earth; let us see how this affects the question. Let us take the case of any living individual: he must have had a father and mother; these also must have had fathers and mothers; and these also; and so on back through the ages to the earliest parents of the human family. We may regard health and disease as coeval with human life; therefore the pedigree of disease is not to be regarded as of recent origin, or its sources traceable to recent influences, but rather to be found in the records of the earliest history of man, wherein we may read the “record of its long descent.” Throughout the ages, and amid the many altered conditions of the earth, man has been much the same as he now is, as far as his subjection to the laws of heredity and variability; the same in barbarism as in civilisation; the same with regard to his health and his diseases; it therefore follows that whilst the influences of heredity are strongest upon him, the more closely he is subjected to the influences of his more immediate ancestors, all the past may be said to slumber in him. We should not therefore regard hereditary descent as affecting only the transmission of the parents’ peculiarities to their children, but also the transmission of qualities derivable from earlier, and even remote, ancestors. How necessary this is we can infer from the frequency with which latent or dormant peculiarities—traceable to some remote or collateral member of a family—develop themselves unexpectedly in some of his descendants; and thus it is that every patient who comes before us is made up of such a mingling of temperaments, idiosyncrasies, and diatheses, as can only be appreciated, and that imperfectly, by even the keenest diagnosis; and of inherited peculiarities of tissue, and function, and dynamism, which may be active or latent; of potentialities or deficiencies which morbid processes can alone reveal.

But to return. Statistics are, and can only be, unreliable and valueless in regard to the percentage of inherited cases of phthisis, and we can only accept the concurrent testimony of every age, which is so strong that it cannot be doubted or rejected. Whole families have been exterminated by phthisis, and, according to Hörlin, as stated by Hirsch, in the island of Marstrand, where only one person had died of consumption during seven years, there were five consumptives then living there, four of them sisters, whose mother had died from this disease. The inherited predisposition to consumption may reveal itself in different ways—sometimes in constitutional delicacy, sometimes in special local affections of the thorax or its organs—and these may or may not be observed at birth or during childhood, but are generally noticed at a later period, as, for example, at the time of puberty, when growth and development are more rapid. However we may subdivide the inheritability of phthisis we cannot but regard it as a factor of prime importance in the etiology of the disease. Although this predisposition is

commoner perhaps among women than men, and its transmission more common through the mother than the father, yet where one parent only is affected fathers transmit more readily to sons, and mothers to daughters, than the converse. Dr. Pollock lays stress on the influence of hereditary predisposition in the acute forms of phthisis, and states that out of 179 cases only 34 could positively declare absence of family taint. Dr. Theodore Williams says the principal effect of the predisposition is to be seen not in any peculiarity of the symptoms, but by the influence it exercises over the age of attack, which is much earlier in those predisposed than in others.

Regarding phthisis as a disease essentially belonging to those which are dependent upon an inherited predisposition, and as the concurrence of several conditions is usually necessary for the development of chronic diseases, we must differentiate between those conditions which are inherited and those which may be acquired. Of the former we must recognise a congenital defectiveness of resisting power, which although not synonymous with weakness, may be associated with it. This is generally manifested in the children of weakly parents, or of closely-related inter-marriages, or when there is a marked dissimilarity in the respective ages of the father and mother, or when repeated pregnancies have followed each other in rapid succession. “Usually in such persons one or several parts of the body are again and again the seat of disease, and form the *locus minoris resistentiæ*. If this be situated in the respiratory organs, frequent and long-continued catarrhs of the nose, larynx, and air-passages occur, and perhaps give rise ultimately to pulmonary diseases which develop into phthisis.”¹ This condition is essentially transmissible, as is also scrofula, another of those conditions which usually concur in the production of chronic diseases.

There is one point of some importance to which I should have referred before, and which I may now be permitted to allude to, especially as it exercises a modifying effect upon the influence of heredity generally, and to a great extent affects the inheritance of disease—viz., that which has been denominated “the tendency to reversion from all variations of specific characters;” for, as the preservation of the specific characters of the species essentially concerns the law of heredity, the determination of individual characters is manifested most in the law of variation: and thus, the inheritance of a disease-tendency, however probable, is not invariable, as disease-tendencies, like parental characters of mind and body, are either held in check or actually neutralised by one of the parents of the child being healthy, so that the constitutional disease of the other may be, in a manner, diluted. “Phthisis,” says Dr. Maudsley, “is a notorious instance, passing so directly from parent to child, as to entail the extinction of a family when it is not neutralised by favourable inter-breeding. For such neutralisation, not of phthisis only, but of other disease-tendencies, may undoubtedly be effected, although we have not at present any knowledge of the laws by which the good result is brought about; the fact, however, is certain, and profoundly significant. The union of two individuals, one of whom has a marked disease-tendency of a particular kind, produces an organic constitution in which it is held in neutralisation or check, never showing itself in their children. It has become a disease-immunity for that generation. Did we know the exact nature of the neutralising process it would no doubt be possible, by suitable arrangements for subsequent breeding, to get rid entirely

¹ Ruehle, *Opus cit.*

of the morbid tendency and to obtain a perfectly sound stock. Unfortunately we do not, and so are liable to find the neutralisation temporary, since it not unfrequently happens that the union of the offspring which is apparently free from the disease-tendency, because it is held in check, with a person who is also apparently free from it, produces an organic nature in which it shows itself distinctly. It is somehow made a disease-aptitude again." Sir James Paget says: "Through such dilutions and such tendencies towards recovery of health in embryo-life, and in a less degree after birth, we may believe that many of the lesser constitutional diseases are derived; but of the rate of diminution in transmission, and of the possible changes of form associated with changes of intensity or quantity of disease, we know very little, if anything. And very little we know of the results of the transmission of more than one constitutional disease to the same offspring. We can often see plainly that the forms in which different persons display a constitutional disease appear very different from those seen in their parents. Thus, in a family of which one or both parents had typical gout, or tuberculosis, or scrofula, there may appear any number of the lesser forms of these diseases, or of the forms deviating furthest from the type. And yet a certain general similarity may appear in all the local manifestations of each constitutional disease thus variously transmitted. They may be unlike in structural appearance while affecting different structures, and yet they may be like in their time-work, or in the production of some characteristic morbid product, or in the influence which medicines or diets exercise on them. These things may prove the same constitutional origin in apparently very different local diseases." This long digression may, I trust, be excused, as I had omitted to refer particularly to those neutralisations or checks to inheritance which frequently resulted from favourable inter-marriages; but it will be seen that although these neutralisations or checks—however they may be perpetuated in theory—are in the majority of instances nothing more than examples of *atavism*, and that the original disease-tendency is transmitted to a generation by heredity, subject of course to the law of variability so far as individual characteristics are concerned.

To return, however, to the further consideration of the diseases of the respiratory system as subject to the influence of heredity, I may regard pulmonary phthisis as a typical constitutional disease occurring in persons of the scrofulous diathesis. When considering the diatheses I was careful to point out that their development, in the great majority of cases, required many generations in which to accomplish it, for they are in reality peculiarities of health amounting to morbid tendencies which have been accumulated and intensified in their long descent so that we can now recognise them as types of constitutions with which are generally associated certain well-known forms of disease. Of these diatheses which were termed universal, because they are not only as old as the race, but because every individual is more or less subject to their influence, are the *scrofulous* and the *catarrhal*; there is surely, therefore, no occasion to prove their transmissibility! These may co-exist or be blent in varying proportions in different individuals, and it may be stated as an axiom that the more the scrofulous diathesis preponderates, the greater the danger of catarrhal attacks in an individual. Mr. Hutchinson has well defined scrofula as a permanent and heritable condition, favouring chronicity in all inflammatory processes, and directing them towards more or less specialised

ends; and catarrh, as inflammatory congestions excited, in a reflex manner, through the influence of cold applied to the surface: therefore, whatever is the result of "catching cold" is catarrhal. He says: "The susceptibilities of the nervous system, however, in this direction differ, as we all know well, very greatly in different individuals. These differences are hereditary, and may easily become the possessions of families or of race. Not only do individuals differ in the degree of reflex susceptibility, but they also vary much as to the special tissues or organs which are most prone to suffer under it. Thus, some catch cold almost solely in the mucous membranes of the nasal passages and pharynx; in others, the tonsils, throat, and larynx are more prone to suffer; in others, the bronchial mucous membrane, etc." To these two diatheses, therefore, I trace the heredity of the majority of the diseases of the respiratory system, for it will be found that by far the greater number of them are included under the heads of scrofulous or other well-recognised constitutional and heritable conditions, and under that of the universally-developed catarrhal diathesis. Thus under the head of scrofulous diathesis may be included chronic tubercular phthisis, acute miliary tuberculosis, pleural tuberculosis, and, perhaps, gangrene of the lungs; whilst under that of the catarrhal diathesis we may range croupous and catarrhal pneumonia, croupous or fibrinous bronchitis, bronchitis, croup, coryza, rhinitis, blennorrhoea, acute and chronic laryngitis, catarrhal tracheitis, bronchial catarrh, pleuritis, tonsillitis, etc. In this list I do not include pulmonary emphysema, and bronchial asthma, which are, however, well-known to be hereditary. Various other so-called diseases of the respiratory organs might be mentioned, as pneumo-thorax, hydro-thorax, hæmoptysis, atelectasis (often congenital), oedema, etc., but as these are for the most merely symptomatic of other diseases, I shall not now further allude to them.

What I am contending for is not that all the diseases of the respiratory system are hereditary or heritable as such, but that in the case of each of them there is a predisposition which is inherited by every individual affected by them; and that this predisposition of tissue, cell or membrane, unless neutralised or held in check by marriage into a different stock, will inevitably reveal itself, and if not in one generation, it will assuredly in the next; for as Dr. Maudsley says: "A disease-tendency, which is latent or dormant at one period of life, or throughout the whole life of the individual, may undergo actual development at a particular physiological epoch, or on occasion of a great bodily crisis from some other cause; and a tendency which is latent or dormant in one generation may show itself in the next generation." Nothing in nature is lost, and whether for weal or woe to the individual, her laws are inexorable, and must be obeyed. Heredity is the law as affecting the character of the species; whilst the individuals are subject also to that of variability, thus necessitating the differentiation of individuals. On the whole, however, we inherit from our ancestors and parents not only our bodies and our minds, but a predisposition to their diseases; and of the latter none more surely than those of the respiratory system. For of the diseases of the respiratory organs, nearly all have their source and origin in the scrofulous and catarrhal diatheses, and these in themselves the result of inheritance in past ages have been handed down to us, modified or intensified as the case may be, by our fathers.

(To be continued.)

LITHOLAPAXY IN MALE CHILDREN.

By E. HURRY FENWICK, F.R.C.S.,

ASSISTANT SURGEON TO THE LONDON HOSPITAL; SURGEON TO ST. PETER'S HOSPITAL
FOR STONE AND URINARY DISEASES.

THE removal of a stone from the bladder of a young child by the crushing operation is not an innovation. *Pari passu* with the improvements and successes of the lithotrite arose the conviction that such methods were not only applicable to the adult, but could be also employed in the child. Civiale adopted the operation, and strongly advocated it.¹ His example was followed by many of his countrymen, notably Jobert de Lamballe. Guersant² published a series of forty cases of lithotrity (thirty-five in boys and five in girls), with three deaths.³ In 1874 we find it a recognised method in France for removing stone in children, being mostly practised at the Children's Hospital in Paris, by St. Germain, Giraldès, and others. Isolated cases are to be found in the literature,⁴ and from these sources a death-rate of 15.2 per cent. has been estimated, a result which contrasts very unfavourably with that of lithotomy in children, the death-rate of which is 6.6 per cent.⁵ Since the introduction of litholapaxy by Bigelow, the treatment of stone in children has advanced by a measurable stride. Not only is the mortality diminished by this crushing operation from 6.6 per cent. to .9 per cent., but also the rapidity of cure is accelerated, and is accomplished in *two to three* days instead of in seventeen to twenty-one days, and that without a cutting operation. The operation of crushing and evacuating the stone at a single sitting, which I am about to criticise and compare with the cutting operation, must become as rapidly popular as the same operation is in the adult, and the firm and recognised position which the former procedure will take, will be owing to the able advocacy and brilliant results of our English *confrères* in India, Surgeon-Majors Keegan, Goldsmith, and Freyer, and in this country to Mr. Walsham.

The valid objections to undertaking *lithotrity* in children are as follows:—The bladder and urethra are so small in children that the operation has to be performed many times before the entire stone is crushed fine enough to become passable with the urine; owing also to the narrowness of the calibre of the urethra, frequent complications arise from the impaction of the sharp-pointed fragments of stone in the canal; lastly, although the ultimate success is good, yet the cure is tedious, and frequently attended with much distress and suffering.

Surgeon-Major Keegan was the first to demonstrate the ease and safety with which calculi in children may be crushed and evacuated at a single sitting (litholapaxy), and has placed on record a series of fifty-eight cases, with one

death. This ease and safety is well exemplified by the following case, which came under my care in November last:—

F. S.—, æt. nine, had had symptoms of stone in the bladder for three years. The calculus could be felt by the aid of a sound, as well as per rectum, to be about the size of a large almond. The meatus was narrow, so that a meatotomy was performed under chloroform, by means of a blunt-pointed bistoury and a No. 12 fenestrated lithotrite passed with ease into the bladder. After three or four crushings the debris was removed by means of a No. 12 evacuating catheter and aspirator ball. The washings showed the faintest tinge of blood. The time occupied was twenty minutes. The stone weighed fifteen grains. The boy got up next day; he passed his water easily and painlessly. He was ready for dismissal on the second day, when a mild attack of scarlatina showed itself, and delayed his convalescence. This case impressed me greatly. A certain number of calculi in children come under my observation every year, and lithotomy has hitherto always been performed. The average duration of convalescence is 18.6 days, and as my former colleague, Mr. Teevan, has pointed out, a most obstinate and long continuing incontinence is apt to appear in one year after that convalescence is complete.

Certain objections to litholapaxy have been brought forward:—

1. *Age*.—It has been thought that the age of the little patient would be an element of danger. The best answer to that are the statistics of age in the 106 cases which I have collected.

Age.	No. of Cases.	Deaths.
Between 1 and 2 years	6 cases	None.
„ 2½ and 3 years	10 cases	None.
„ 3½ and 4 years	13 cases	One.
At 5 years	16 cases	None.
Between 6 and 9 years	34 cases	None.
„ 10 and 15 years	27 years	None.
	106 cases.	1 death. <i>i.e.</i> , Mortality = .9 per cent.

2. *Size of Urethra*.—It was supposed, but disproved by Surgeon-Major Keegan, that the size of the urethra would be too small to allow of the introduction of lithotrites and evacuating catheters sufficiently large to perform the work. Cases at the following ages permitted the following sized instruments to be passed after incision of meatus:—

Age.	Size of Lithotrite (English Scale).	Size of Evacuating Ca- theter (English Scale).
1 year, 3 months	No. 6 (E.)	No. 6.
1 year, 9 months	No. 9	No. 6.
1 year, 9 months	No. 7	No. 7.
2 years, 3 months	No. 7	No. 7, 8, or 9.
3 years, 4 months	No. 8	No. 9.

Some boys have peculiarly large, and others particularly small urethræ—a varying condition which I have reason to believe is due to heredity. Each urethra must be judged on its own merits, none tally with a fixed standard. It is only after narcosis and incision of the narrowest part of

¹ Lithotritie, pp. 266 et seq. “Ces petits instruments avaient paru faibles à quelques personnes, mais les craintes disparurent lorsqu'on vit des enfans, même très jeunes, être opérés avec succès par la nouvelle méthode. En 1827 je fis une opération de ce genre sur un enfant de sept ans, très peu développé, et qui portait une grosse pierre. Elle eut lieu à l'hospice de perfectionnement, et fut couronnée d'un plein succès.”—p. 267.

⁴ Porta de Pavie. *Union Médicale*, 1874, September 29th.

⁵ We do not include the brilliant and unequalled results of Freyer in India, who has had 143 cases of lithotomy in children without a death.

the urethra—i.e., the meatus—that we can select the proper sized lithotrite which the case before us will safely admit.

3. *Size of Stone*.—A large-sized stone was supposed to be an insuperable difficulty. This belief is at once overcome by the record of a stone weighing 700 grains, successfully removed from a boy æt. nine and a half years by Surgeon-Major Caldecott. The chance of meeting large stones in children is fortunately small. Thus, in only 21 per cent. of the cases did the stone weigh between 100 and 200 grains, in 8 per cent. of the cases between 200 and 300 grains, and in 3 per cent. of the cases between 300 and 400 grains.

The size must of necessity depend upon a variety of causes, such as the duration of its formation and the nature of the urine, but it is useful as well as encouraging to note that the stone in children is *usually small*, and that if large stones are met with, it will be in direct proportion to the age of the patient; so that roughly speaking we may say, *the larger the stone is, the older is the patient, and the greater is the size of the lithotrite allowed*. Both these points may be tabulated as follows:—

Age.	Weights of stones crushed, in grains.	Rough practical calculation.	Percentage calculation.
Under 2 yrs.	18 15.....	All under 20 grs.	100 per cent. under 3 js.
At 2 years	7 8 10 11 24 30 32 ..	40 grs.	80 " " 3 js.
At 3 years	12 14 16 19 38 50 52	100 grs.	70 " " 3 i.
At 4 years	27 30 35 38 55 115 136	140 grs.	71.4 " " 3 i.
At 5 years	17 20 27 36 30 32 34		
	41 45 51 84 85 116		
	140 158	150 grs.	66.6 " " 3 i.
At 6 years	10 14 23 50 65 72 105		
	210	210 grs.	50 " " 3 i.
At 7 years	5 14 30 30 57 72 122		
	140 148 160 166 220	230 grs.	41.6 " " 3 i.
At 8 years	15 16 28 45 95 176 285	300 grs.	57 " " 3 i.
At 9 years	90 145 158 700	None " 3 i.
At 10 years	9 22 30 43 80 100 136		
	170 190 200 270 360	360 grs.	58.3 per cent. " 3 ii.

4. *The Hardness of the Stone*.—This has more than once forced the operator to substitute lithotomy for the proposed litholapaxy. But it is not often that a stone in a child's bladder cannot be crushed. In four of the 106 cases it is specially noted that the stone was "very hard."

The composition of the calculus must always depend upon a variety of causes, such as food, climate, diathesis, and co-existing cystitis; but it is not unpractical, as regards the "crushability" of the average stone, to grasp perceptibly an idea of the hardness we may have to encounter. Thus:

PURE STONES.

Oxalate of lime calculi (i.e., the hardest)	were met with in 13.5 per cent. of the cases.		
Uric acid calculi	"	"	45.5 " "
Phosphatic calculi	"	"	13.5 " "

COMPOSITE STONES.

Mixed oxalates and phosphates	met with in	3.	per cent. of the cases.
Mixed oxalates and uric acid	"	7.5	" "
Mixed urates and uric acid	"	1.5	" "
Mixed urates and phosphates	"	12.1	" "
Mixed uric acid, oxalate of lime and phosphate	"	3.	" "

From this we infer that in 13.5 per cent. of the cases, we may encounter the toughness of oxalate of lime: but the greater proportion are uric acid (45.5 per cent.), and 86.5 per cent. are easily crushable.

Contra-indications to Litholapaxy in Children.—Presupposing that the surgeon is used to lithotripsy in the adult, and has a light and dexterous hand, these contra-indications are only three in number: (1) a very small-calibred urethra not admitting even a No. 5 English lithotrite; (2) a very hard, or very large stone, or one with a nucleus of a foreign body; (3) a contracted and diseased bladder. Two of the contra-indications can be established by rectal examination. Thus the size and shape of the stone, and its position in the bladder, can be readily estimated per rectum, and the tonicity and dilatibility of the bladder also appreciated by the same means. It is not too much to insist upon that a careful examination of the patient, and his history, is essential to an unbroken series of successful cases. Thus the one fatal result out of 106 was caused by operating upon a case undoubtedly fitted for lithotomy rather than litholapaxy.¹

Gotia, æt. four, was pushed down in a field by a companion, and with the force of the fall a piece of the stalk of the tilli² penetrated his anus, pierced the bladder, and broke off in that viscus. A stone, three-quarters of an inch in length, formed round it. Mr. Ginput Singh crushed it, and, at subsequent sittings, pieces of the tilli stalk were removed in the jaws of the lithotrite. The boy died, and it was evident that, had a more careful examination of the history and the case been undertaken, the boy would have been subjected to lithotomy rather than litholapaxy.

Certain golden rules may be laid down for litholapaxy in children:

1. Examine carefully, per rectum, to ascertain size of the stone and the condition of bladder.

2. Let your decision, as regards the advisability of litholapaxy, be made subject to the size of the urethra and the hardness of the stone—estimating both while the patient is under chloroform.

3. Never *force* the lithotrite through the meatus. Incise the latter. (Keegan.)

4. Select invariably a *completely fenestrated* lithotrite. (Keegan.)

5. Use the lightest of hands, work towards the posterior wall, and let your crushing be thorough.

6. Remove *all* through an evacuator catheter carrying a stylet, using the latter to rid the eye of any sharp particle which may cut or lacerate the delicate urethra during the removal of the instrument.

Litholapaxy v. Lithotomy.—Keegan writes "I would almost as soon think of performing lateral lithotomy on an old man, the subject of a small uncomplicated stone, as I should think of performing lateral lithotomy on a boy whose urethra readily admitted the passage of suitable lithotrites and evacuating catheters, and whose stone was neither abnormally hard or large." This opinion I would most warmly endorse, and I would tabulate the differences between the two operations as follows, to show at a glance

¹ *Indian Medical Gazette*, 1884, p. 135, May.

² *Didymia angiospermis* Sesamum, Schreb-gen N. 1048. An annual, growing in a good soil to three or four feet high.

the results which bear testimony to the solidness of that opinion:

Operation	Percentage of deaths	Causes of death	Complications	Average length of time recovering	Pain	Advantages	After-results
Lateral Lithotomy	6.6 per cent.	Peritonitis Eight per cent. cysto-pyelitis and nephritis Six per cent. intercurrent	Perforation of urethra Rupture of urethra Hæmorrhage Wound of rectum, etc.	17.6 days (Keegan) 18.9 days (St. Peter's (London))	Vari-able	Complete removal	Incontinence (Teevan) Emasulation (Langenbeck)
Lithotripsy	15.9 per cent.	Two months	Great	..	Many attacks of cystitis, orchitis, retention, etc.
Litholapaxy	.9 per cent.	Nephritis	Nipping of bladder wall in one case	Next day well and up Discharged in 7 days (Keegan) 4.5 days (London)	Nil	Rapidity of cure No cutting operation	Nil

MEDICAL ETIQUETTE.

BY ALFRED J. H. CRESPI, WIMBORNE.

FORMERLY EDITOR OF THE "SANITARY REVIEW."

THE doctor's life is a long contest—a contest with disease, and trying to hold his own and get a livelihood. In hardly any other liberal calling is the conflict so embittered, and in no other is the estrangement between rivals so undisguised and so prominently and persistently forced upon the notice of the general public. Having had many and unusual facilities for seeing the strained relations of medical practitioners in different parts of England, having indeed forty-three times had sole charge, usually without remuneration, of practices in Yorkshire, Lancashire, Cornwall, Hereford, Berkshire, Gloucester, and I can hardly, without an effort, recall all the other counties, I have often been both pained and surprised. I have, moreover, in the course of this work attended all grades of patients from club and parish clients up to the families of bishops, judges, peers, and presidents of the British Association, and I have also acted as *locum tenens* to men who were

brothers of bishops, and cousins of men of title, so that my opportunities have been more numerous and varied than fall to the lot of most men.

Medical etiquette is—in plain English—nothing but the golden rule, "Do to others as you would that others should do to you," in other words that etiquette, which to the public is so puzzling and which fills so large a portion of medical life, and, let me add, of the medical papers, rests upon a golden Gospel precept. So far so good, and were the rules of etiquette better defined, more easy of application, and were not the disintegrating influence of medical life so far-reaching and difficult to counteract and avoid, they would be of inestimable advantage to the profession and to the public. As it is I fear that they are more often heard of than practised, and that they are too frequently used as a cloak for much unbrotherly and ungentlemanly conduct.

A medical career lacks, and always must lack, those social advantages which attract many able and accomplished men to other liberal callings. Not that medicine is not a useful occupation, one affording ample scope to the powers of the most enlightened and far-reaching mind. I cordially endorse the words of Sir James Paget, when he says, "that I dare to claim for medicine that, among all the sciences, ours in the pursuit and use of truth, offers the most complete and constant union of those three qualities which have the greatest charm for pure and active minds—novelty, utility, and charity." The pecuniary emoluments of medical practice are probably generally in excess of those of the Army, the Bar, and the Church, though it may be decidedly less than those of solicitors. But the doctor has to earn his money in the sweat of his brow, with unceasing expenditure of labour, anxiety and trouble. He is never out of harness. His duties are often most onerous and disagreeable, and they engross his thoughts and his time more than do those of the majority of other professional men, indeed, it would be possible to maintain, though of course a man knows the unpleasantnesses of his own calling better than he does those of others—that the doctor's life is, as a broad rule, less socially attractive than that of any other professional man. It has been long lamented that the public recognition of these truths is not more keen and generous. Able medical writers, like the illustrious Dr. Gregory, acutely feeling the drawbacks of medicine, and the want of precision and loftiness of aim of many medical researches, have not hesitated to write as he did, that "I think it more than probable," that is absolutely certain, "that in fifty or a hundred years the business of a physician will not be regarded in England as either a learned or a liberal profession." While Sir Richard Blackmore, when a young man, having inquired of Sydenham, that famous practitioner of his day, whose name is still familiar to us in connection with the Sydenham Society, and the originator of the phrase "the natural history of disease," what books he would advise him to read on medicine, was startled to be told "Don Quixote." It was not too severe a comment on the part of Johnson, in his life of Blackmore, when he accused Sydenham in this reply of falling far below the dignity of his profession. Johnson wisely and impressively added, "The perverseness of mankind makes it often mischievous in men of eminence to give way to merriment; the idle and the illiterate will long shelter themselves under this foolish apophthegm." Sir William Hamilton, of course not writing with any practical knowledge of medicine, although he had among his personal friends many of the

foremost medical teachers and practitioners of his day, contributed a famous and brilliant essay to the *Edinburgh* of 1832, with the avowed object of showing that medicine had made no material progress since the days of Hippocrates, a proposition that I shall neither pause to maintain nor to combat; my object in giving these quotations is to show the small respect often expressed for medical studies and medical practitioners.

Candidly medicine is not a favourite pursuit of the rich, the powerful, and the high born, and from the exacting nature of the duties which it imposes upon its professors, they speedily, I fancy, settle down as practitioners, mainly striving for an income. Unfortunately their sphere of labour necessarily overlaps that of other men similarly engaged in their neighbourhood, and, moreover, the most eminent practitioner has no immunity from the annoyances of practice, and may be discarded at the caprice or whim of a patient for another. I have known illustrious men thrown overboard for men of far inferior social and professional attainments and position. A friend, and subsequently a client of mine, once had Sir Thomas Watson and Sir William Jenner in independent attendance on a sister of hers, and after a time the former received his congé with little delicacy.

The rules of etiquette in theory are plain enough. Any doctor can set up anywhere; he must not advertise, run down his brethren, or misrepresent his own qualifications and experience. He can apply for any appointment for which he is eligible. On settling in fresh quarters he calls, as soon as possible, on his neighbours; in the open country that may mean going over an area of ten miles radius. In a small town he calls upon all the local men; in a larger one, upon those in his immediate neighbourhood; while in a great town or in the metropolis, especially in the medical quarters, he confines himself usually to his immediate neighbours and to acquaintances, the professors at his school, or those connected with any society or association with which he has relations. His friends and those medical men, whom he has called upon, in due course call upon him, and from that time he is supposed never to disparage any of his brethren, never to use any unfair arts to supplant them, not to attend any one who is the client of any other practitioner, and to insist upon consultations in all serious emergencies. In short he must be scrupulously considerate and long-suffering in all the concerns of medical life. Of course his brethren are presumed to act in like manner towards him. So far the theory.

Now about the practice. In small towns, and in the open country, if a man sets up and does not buy a practice, and of course he may want to settle in a place where there is not a practice for sale, his arrival is often like that of a fox in a hen-roost. His brethren resent, as a dire insult, his arrival among them. Perhaps they are all struggling for a bare livelihood, pressed to meet bills and keep down expenses; perhaps they have spent a large sum in buying a practice, or they have succeeded to an old-established position, or they have sons or relations they want to introduce to their own clients. The new doctor calls: one man receives him, his face red like a turkey cock's, his hair bristling, animosity depicted upon every lineament. "I am Mr. Jones," timidly says the caller, "and I have settled here in practice." "Oh," retorts the host, "Who told you to settle here? This is the worst place in all England; wages low; half the people going to hospitals; the Mudtown and Downhill fellows are

eternally here; you won't get a livelihood in ten years. Of course," and this with a vicious glare, "you know that in such a place as this any patients you get must be taken from the other men. Why on earth didn't you go to Swinford, there's plenty of room there." Five minutes ends the pleasant interview; the visitor is generally not asked to sit down, and when he is marshalled to the door the slam with which it is brought to, tells him significantly enough that he is not wanted there again. Some of the local surgeons don't return his call; others send a card by post. This is very common in towns of 60,000 or 80,000 people, while other practitioners will simply leave a card declining to enter. The new comer soon finds that his brethren do not talk graciously about him; his qualifications, motives, and antecedents are usually disparaged. If he chances to get a few patients he soon discovers that they are claimed by the older practitioners, and he has to transfer them, getting black looks and no thanks; in short, he is made to feel that he is an interloper and not a brother.

Am I going too far? An F.R.C.S. of some repute died a few years ago in a small town; that man was a Church governor and a good deal besides, and a great stickler for medical etiquette, but he is reported never to have noticed or called upon, or had any relations with a surgeon, who had set up in the same little town a dozen years before the senior's death. Again, a friend of mine once spoke to me in biting terms of the "scamp, rascal, impostor, and villain," who lived opposite to his front door. That objectionable person, however, I happened to be aware was a personal friend of people well known to me, and when I made enquiries I found that he was an excellent, well-qualified and accomplished man, but *here* was the offence, he had eight years before, set up, as he had a perfect right to do, in that rapidly increasing town, and thus he added another to the local small contingent of rival doctors.

As a *locum tenens* it has been distressing to find men, otherwise fairly respectable and well-behaved, at deadly enmity with all their medical neighbours. I once found a superior man in Lancashire at daggers drawn with ten other brethren, all, according to him, "drunkards, profligates, and imposters;" and I can call to mind eight or nine good enough men, who live isolated lives, professionally at any rate, having nothing to do with the two or three surgeons in their several neighbourhoods. In larger towns matters are not so bad, but even there antagonism is great, and at best there is often little more than an armed truce, liable at any moment to break out into open hostilities. Anything like friendly union is most rare, and any approach to confidence and mutual help is indeed a phenomenon. Every practice is a close preserve, every doctor fancies he has a vested interest in his clients, and any little bad turn he can do his neighbours he is only too ready to make the most of, indeed the relations are so strained that it is of no use for an outsider to try to make peace. In violent contrast with the tension due to a struggle for existence and the suspicion entertained towards his immediate neighbours is the warmth of the relations subsisting between him and medical friends some way off; where personal rivalry ceases to be felt there is room for devoted friendship and mutual regard.

There is no question in my mind that medical men would be great gainers, personally and socially, were they to cultivate greater confidence in their neighbours, and were there more giving and taking. As for the general public, the sneers with which they often ridicule the cat

and dog life of local practitioners are not pleasant to listen to. No medical man should forget that a practitioner has a full right to set up anywhere. If a new comer does not buy a practice, he has a long and severe struggle, indeed, usually speaking, no course when it can be avoided is more imprudent than trying to work up a general practice. The fresh comer has exceptional difficulties, and spends three or four times as much, in the long run, as would have enabled him to start as the partner of, or the successor to an old-established practitioner. When a practice is not purchased, the new comer has long to wait before he is in the running at all with his rivals; they are far ahead of him, and any ill feeling on their part is most unkind and uncalled for.

What happens if a practitioner does loyally transfer cases to the men who seem to have some claim to them? Let me try to show. In many cases it must never be forgotten that when a new practitioner is called in there are private reasons which cause that course to be taken. It may be that the old practitioner is getting disliked, or that some tension exists, or that a change is desired. A younger practitioner is called in; perhaps the house is a good one, and the introduction is valuable. On making enquiries he learns that up to that time someone else has attended; he is not informed why he has been called in; very likely full of notions of medical etiquette he goes off to the former practitioner and transfers the case. From a long experience in Birmingham I can say that never once did I get cordial thanks for so doing. I was always regarded as a kind of interloper by the doctor who resumed attendance, while I often entirely lost the family and never got called in again. I remember once visiting at a friend's, in South Down. The house was large and handsome, there were many guests, and the first day I was just sitting down to dinner when a servant came in with an urgent message for my host. In a minute or two he returned, "I am so sorry to tell you," he remarked, "that a friend of mine, an officer, the son of the Squire, has just had a fit, and his sisters, knowing you were here, have desired me to ask you if you would kindly go and see him." My friend continued that the family was one intimately known to him, and that it was very wealthy. I demurred to going. I was a stranger, besides no doubt they had a medical attendant. Well, I had to leave my untouched dinner, and to trudge some way in the mud and darkness. Arrived at the house I found a gentleman in strong convulsions, and I had no alternative but to remain till late at night watching over him. Now I do not like such cases, and I should have preferred transferring the sufferer to his own doctor. At eight next morning I called again, and later on in the day a second time, seeing the family. I was warmly thanked, offered any fee I liked to ask, but, as I managed to find out that though a Plymouth consultant often came, the more ordinary attendant was an elderly practitioner a few miles off, I declined, telling the friends that I was acting for the latter. After paying another visit or two, I, on the third or fourth day, marched off to the family doctor, a graduate in arts and medicine of one of our ancient universities. I found him living in a large house, and it was perfectly obvious that he was in affluent circumstances; he received me pleasantly enough till I explained who and what I was and why I had called, then his countenance changed: a dark frown overspread it; his voice became sharp and his words curt. "You need not trouble yourself about my patient; it is no business of yours; you should have sent for me at once; I will go off and see him this afternoon."

He rose; I was hurried to the door, and when I got into the street I felt for the fiftieth time in my life what hollow imposture medical etiquette too often was. I had lost a good dinner, and the company of a large and pleasant society; had passed some hours supporting the head of a powerful epileptic; paid three or four tedious visits; refused four or five guineas, which would have been most useful to me, and then was only rudely told to mind my own business, and blamed for not sending for a man, a total stranger to me, and about whom I did not learn anything for two or three days, and at last when I went to him it was plainly in opposition to the wishes of the family.

A well-known Gloucestershire surgeon, a man of iron resolution and boundless self-assurance, used to stand on little ceremony. I have been assured that he never hesitated to attend all the other doctors' patients in the district. He would lift his big forefinger and exclaim, "Another twenty-four hours of that man's attendance and you would have been a dead man." But then Mr. Nemo was too important a person to be trifled with, and his colleagues feared him. I do not advocate that kind of thing. But I do want some practical good to come from my paper, and, therefore, I will sum up briefly.

In the first place the medical profession is very full, the competition keen and the expenses of practice large. Every practitioner is trying to hold his own, to make a living, and to turn his opportunities to account. Men rarely practise medicine simply for pleasure as men may remain on in the army to enjoy the companionship of the mess, or as barristers may go on circuit for the pleasure of the life, or as clergymen will often hold livings for the sake of doing good in a pleasant and respectable fashion. No; the young, and the old doctor too, cannot be expected to shut himself up, refusing fees, declining to enter houses which other men may fancy are their peculiar province, and letting years slip rapidly away. So far true; at the same time there is a distinct loyalty to the calling and to one's brethren that every man should try to keep intact; he must give and take, holding out a helping hand, not resenting, as a deadly insult, any little piece of good fortune that befalls a younger brother. He should religiously guard himself against criticising the treatment and conduct of his rivals, especially when he has only the garbled and untrustworthy versions, which more or less dissatisfied patients give him. If he listens to their absurd tales, as I much regret to say most medical men will do, even the highest, if he permits himself to comment, as most practitioners will do, on the untrue reports of patients and their friends, he will cause serious annoyance and do much harm in more ways than one. When brother practitioners do him a kindness he should meet them in good part, frankly, cordially, and kindly; it will be quite time enough to show the cloven hoof when he finds that his brethren are not to be relied upon. Unfortunately there are in the ranks of the profession a large number of unscrupulous and dishonest men; men dead to all the higher qualities of human nature; men who will pay a visit once a week or three times a day according to the pecuniary circumstances of their clients, and without regard to the gravity of the symptoms; men who will malign a rival and traduce a friend; men who will take to the utmost letter of the law, but who never give one iota. These men are often the most successful practitioners, and are held in great esteem, and they are sometimes highly qualified, and most skilful, and hold important posts. These men are providentially in a minority, though they exist everywhere; with such

men as these, friendly relations are hardly ever possible.

Lastly, whenever a practitioner finds himself discarded, more or less courteously, for another practitioner, let him not blame the latter without due cause. Clients often hesitate to explain why they change: there may be good reasons, severe tension, I know not what, or mere caprice, especially in the case of that large class of imaginary invalids who delight to pour into a fresh ear their complaints, and long for another string of medical rules from still another adviser. Not seldom when friendship is waning, confidence being undermined and a change is desired, it is better to part amicably, preserving kindly relations to the last, and ever remembering that the doctor is the employed and the client the employer. But though all this is true, medical etiquette, liberally interpreted, generously acted upon, has great uses: it should govern the relations of the old as well as of the young; we must adopt it ourselves as well as expect others to comply with it; and we must guard against the too common error of expecting that our medical friends should be tightly tied down by its requirements, while we, on our part, feel at liberty to act as we like.

MONTHLY REPORT ON NEW PREPARATIONS, FOODS, DRUGS, INVENTIONS, ETC.

Liq. Podophyllin (Hockin); Liq. Podophyllin et Pepsin (Hockin); Liq. Podophyllin et Belladonna cum Strychnia (Hockin).—The above three preparations, prepared from the purest drugs, and miscible with water, infusions, etc., have been very favourably received by the profession. The *Liq. Podophyllin* will be found particularly useful in that large class of patients whose sufferings and symptoms depend on what we frequently call inactive liver. For efficacy and for convenience and elegance of dispensing we can recommend this preparation. The changes may be rung, in those cases which require a combination, on the other mixtures—for instance, in cases of chronic constipation, the strychnia combination will be found most efficient, while in other cases, associated with impaired digestion and general debility, benefit will be derived from the pepsin compound. In connection with this class of preparations we may allude to a question often asked us: "Should physicians prescribe these compounds?" The *St. Louis Medical and Surgical Journal* has very ably treated the question, and we give the following extract from the able article that has appeared in that journal. The editor first asks:

Why should a physician resort to these ready-made prescriptions at all? Why does he not draw upon his own knowledge of applied therapeutics, and write out his own formulæ in every case? Why does he prescribe this one's sugar-coated pills, or that one's gelatin-covered granules? Why, indeed? Simply because he knows that these articles, being made in vast quantities, by improved apparatus and appliances manipulated by highly-trained and educated employes, and directed by skilled chemists, can be made better, more accurately, and far cheaper than they could be compounded by the most skilful prescriptionist. He does it for the same reason that he buys a watch ready-made from the jeweller, or a buggy ready-made from the carriage maker. The gist of the whole matter depends upon what is meant by the term "proprietary medicine." In its limited and best sense we understand by the term a remedy of which the ingredients and their proportions are made known to the profession, and the trade or proprietary name of which is alone protected by law. When such preparations are made exclusively for the use of the medical profession, and are advertised exclusively in medical journals, we cannot see any possible lowering of professional dignity, or deviation from "time-honoured principles of medical ethics" on the part of the physician who uses them in his

daily practice or who recommends them in his communications to medical journals. The name, in this class of proprietary medicines, is to be regarded simply as the guinea's stamp—a guarantee of the purity and genuineness of the product, and the registration of it; patenting it, if you please, is as much for the protection of the physicians who use it as for the parties who manufacture the remedy. It in no sense makes the drug a "patent medicine" any more than does the writing of "Fairchild" before pepsin, "Merck" before or after an alkaloid, or "Schering" or "Squibb" before chloroform, transfer these chemicals into that category. These men—Merck, Schering, Fairchild, Squibb, and a few others—have devoted their lives and spent enormous sums of money in making their products the purest and best that can be attained by human honesty and human ingenuity; and as a reward their names attached in copyrighted labels to their chemicals stand as a perpetual guarantee to the physician and patient against the fraud and greed of less honest manufacturers; and it would be a great injustice to them, as well as to the profession and public, to deprive them of this guarantee.

Clinical Cases.

THE STANLEY HOSPITAL, LIVERPOOL. REPORTS OF SURGICAL CASES.

BY ARTHUR H. WILSON (ASSISTANT SURGEON).

I. Congenital Cystic Hygroma.—Margery K—, æt. six, a healthy looking child, was brought with a lump about the size of a hen's egg under the right clavicle. The swelling was first noticed when the child was two years old, but recently had begun to enlarge somewhat rapidly. The arm seemed weak; the veins over tumour distended, and there were two translucent bluish spots, suggesting fluid contents; it felt lobulated, and seemed to be under the pectoratis major; no fluctuation; movable in an upward and downward direction, but not laterally. On October 19th, 1885, patient was placed under chloroform, a skin incision about two inches long made, and the pectoral muscle divided. The tumour was at once visible, resting on the ribs, and seen to consist of a bunch of cysts, none of them larger than a marble, the majority about the size of a pea. Nearly all the cysts were filled with clear serum, but some of the larger with dark blood-stained fluid. The tumour was firmly fixed to the clavicle, and its removal was tedious, partly with the knife and partly by tearing. A prolongation was traced towards the axilla, and at the end of it (about two inches from the main tumour) three large cysts were found and dissected out. The tumour appeared to be freely removed. Listerian precautions were taken.

Remarks.—The case did well, except that a large inflammatory swelling formed in front of the shoulder, but subsided under poultices. The prolongation into the axilla is of interest, as the child's friends stated that the lump first appeared in the arm-pit, and "moved up" under the clavicle. At the end of last year (two years since operation) patient showed no signs of recurrence.

II. Epithelioma of Scrotum.—John K—, æt. forty-eight, an engine stoker, admitted May 27th, 1887. Disease began about eighteen months ago as a wart, and was very irritable. Until three months ago it remained about the size of "an ordinary coat button," but since then has grown rapidly. It now presents a large ragged surface, about two inches by one inch, on the left side of the scrotum, the testicle being adherent. On the right side are two isolated growths of the same character, but of small size, the testicle being free. No enlarged glands in either groin, and none to be felt in the pelvis. On May 27th, the whole mass was freely removed, together with the left testicle, which was firmly adherent to

the growth, the cord being carefully freed and tied with strong catgut. Sufficient scrotal skin was saved to cover up the right testicle, a large drainage tube inserted, and salicylic wool dressings applied. The patient did well, and was discharged in a month. Up to the present time there is no sign of recurrence. *Microscopical examination* showed a typical epithelioma, with unusual abundance of cell nests.

Remarks.—This simple case of epithelioma of the scrotum seems worth recording as an example of true “chimney sweep’s” cancer occurring in a stoker. Among stokers on board ship, after a voyage of some duration, it is common to see men with sores and ulcers on the scrotum, groins, or inner upper-third of the thighs. My attention was first drawn to these through having invalidated a man for them, much to the indignation of his fellow-stokers, several of whom declared they were “quite as bad,” a statement which I was able to verify. Although in sweeps the disease is now less frequent, experience may show that among other workers in coal dust, the reverse holds good. On the fourth day of the after-treatment the wound became septic, and in this case—as in several others—immediate benefit was derived from the injection of iodoform in oil into the wound.

LEICESTER INFIRMARY.

NOTES ON NINE CASES OF COMPOUND FRACTURES OF LEG, AND TWO COMPOUND COMMINUTED FRACTURES OF FOREARM. ANTISEPTIC TREATMENT. RESULTS.

By J. B. OKELL, M.R.C.S., L.R.C.P. (HOUSE SURGEON).

J. M——, male, æt. twenty-three, a collier, was admitted May 12th, 1887, suffering from a severe compound comminuted fracture of tibia and fibula, about the middle third. The vessels being intact, it was determined to try and save the leg; so ether being administered, the wound was enlarged, in order to examine more thoroughly the injury. It was found that the bones were much comminuted, and periosteum stripped off for some distance. About an inch and a half of tibia, and several pieces of fibula which were found lying loose, were removed. The wound being well washed out with carbolic lotion (one in twenty), a piece of drainage tube was inserted, and the leg put up in a box splint, having been dressed with loose wool and the wadding (this kind of dressing was used in subsequent cases, together with carbolic spray). On May 14th, dressing was changed and the tube taken out. From this date the temperature remained normal throughout. This last dressing was not changed for nearly three weeks, when boracic acid lotion was substituted, as there was now a large healthy granulating surface, and some bare bone to be detected. In the middle of July he was just able to raise his leg off the splint. At the beginning of August the leg was put up in a well-padded Bavarian splint, with a window to allow for the dressing of a small sinus. On August 20th, he was discharged. At the beginning of September he was next seen, when it was found that he had crutch palsy. The sinus was healed, a piece of bone having come away. The paralysis was cured by the battery, after a month’s residence in the Infirmary. He was now able to get about with two sticks, but required the support of plaster case. At the beginning of December the leg was practically sound.

E. C——, female, æt. six, was admitted on September 20th, with compound fracture of tibia and fibula in the lower third, caused by some heavy logs of wood falling upon it. The tibia was protruding through the wound, and the peri-

osteum stripped up for some considerable distance. Chloroform being administered, the wound was treated as the preceding case. The dressing had to be changed next morning, as it was through, but not again for nearly three weeks, when wet dressings were substituted on the granulating surface. At the beginning of November a large scale of bone, measuring two inches, came away, when the wound rapidly healed up. On November 28th, the leg was put up in a plaster of Paris bandage, and patient was discharged next day. Next seen on December 28th, when the bandage was taken off, and patient was able to walk well, without any supports whatever.

E. B——, male, æt. seventeen, a very strumous lad, with enlarged glands in neck, was admitted on September 21st, with compound separation of epiphysis at lower end of tibia, with much protusion of upper end. Ether having been administered, the bones were reduced into good position by forcible extension. This was then treated as the preceding case, excepting that dressings had to be more frequently changed. The temperature varied between normal and 99.8. Notwithstanding his very strumous condition, firm union took place; but a small sinus was left, leading to some bare bone. On November 10th, the leg was put up in a Bavarian splint, with a small window for dressing; and on November 21st, he was sent to Scarborough Convalescent Home. On December 20th, he was again seen, and was able to walk on the leg, but the scale of bone had not come away. On January 13th, Bavarian splint taken off, wound entirely healed; free movement in ankle joint; can walk without crutches.

W. D——, male, æt. fifty-one, a collier, was admitted on September 23rd, with a compound Pott’s fracture, having great displacement of foot outwards. This was reduced by forcible extension, and treated as the preceding case, the dressing not being changed for fourteen days, the temperature keeping normal. It was found that the wounds had almost healed, excepting for some superficial sores, which healed in a few days with wet dressings. Firm union had taken place by November 9th, when the leg was put up in a Bavarian splint, and he was discharged on November 12th, being next seen on December 14th, when the plaster was taken off, and the patient was able to walk very fairly well.

E. C——, æt. forty-four, a collier, was admitted on October 4th, with a compound fracture of tibia and fibula at the junction of middle and lower thirds, with protrusion of upper fragment of tibia, and stripping up of periosteum. Ether being administered, the wound was enlarged, and by extension the bones were got into good apposition. This was then dressed as the preceding cases, but the dressing was changed next morning, as it was through. The temperature keeping normal, this was not changed for three weeks, when all was found healed, excepting a small sinus leading to bare bone, so wet dressings were substituted. Firm union having taken place, the leg was put up in a Bavarian splint, with a small window, on November 23rd, and the patient was discharged on November 26th. He was next seen on January 7th, when the wound was perfectly healed. The Bavarian splint was taken off, and the patient was able to walk on the leg.

J. H——, male, æt. forty-one, a waggoner, was admitted on October 11th, with a compound fracture of tibia and fibula at the junction of middle with upper thirds, with protrusion of upper end of tibia, and stripping off of periosteum. Ether having been administered, the wound was enlarged, and by

forcible extension the bones were brought into good apposition. This was then treated as the preceding cases, dressing being changed next morning, and a large clot of blood washed out. This dressing was not changed for three weeks, when the wet dressing was substituted. On November 23rd, he was able to just lift his leg off the splint; so it was put in a Bavarian splint, with a small window, and the patient was sent to Folkestone Convalescent Home on November 29th. He was next seen on January 6th, when there was firm union. The sinus had not healed up, but patient was able to stand about on the leg.

J. C——, male, æt. seventeen, a waggoner, was admitted on October 27th, with a compound fracture of tibia and fibula in the middle third, a simple fracture of femur on the same side, a simple fracture of inner third of clavicle of the opposite side, and some bruising of the abdomen, caused by a cart load of soil falling back upon him. Ether having been administered, the compound fracture was treated as the preceding cases, but dry dressings had to be discontinued in a week, as the skin on the leg had sloughed for some distance, owing to the bruising it had received. The femur was put up in a Bavarian splint, with a long outside splint from the axilla; the clavicle was treated as ordinarily, the temperature remaining normal throughout. On November 24th, good union had taken place in all the fractures, and the ulcer caused by the sloughing of the tissues, which extended half way round the leg, had taken on a healthy granulating surface. By the end of December, the ulcer had entirely healed, so the patient was discharged on January 4th, being able to get about well on crutches.

E. G——, female, æt. ten, was admitted on November 1st, with a compound fracture of tibia and fibula in the middle third, protrusion of tibia, and stripping up of periosteum. Chloroform being administered, the bones were brought into good apposition, and the leg put up as in preceding case. It was dressed next morning, as it was through, the temperature remaining normal. This was not changed again for nearly a month, when wet dressings were substituted, it all having healed, except a sinus leading to a small scale of bone. The leg was put up in a Bavarian splint on January 6th, and patient was discharged on January 7th, being able to get about well on crutches.

E. L——, male, æt. twelve, was admitted on November 25th, with a compound fracture of tibia in the middle third. Chloroform having been administered, a counter opening was made in order to afford better drainage. It was then treated as the preceding case. The dressing was changed on November 28th, and the drainage tube taken out. In two days more the dressing had to be removed, as it was through, but not again for fourteen days, as the temperature remained normal, when wet dressings were substituted. By the end of December there was firm union. One of the openings was all healed up, the other nearly so. The leg was put up in a Bavarian splint on January 9th, and patient was discharged on January 14th, wound healed, being able to walk with crutches.

C. H——, male, æt. nineteen, carter, was admitted on April 21st, with a compound comminuted fracture of radius and ulna. Ether having been administered, it was dressed as the preceding, in this case anterior and posterior straight splints being used. As the temperature was normal, it was not dressed for a fortnight, when the wound was found entirely healed up; and as the patient was most anxious to

get back into the country, he was discharged on May 7th. He was last seen at the end of June, when he had a very straight and useful arm, being able to follow his old employment.

E. L——, male, æt. twelve, was admitted on November 1st, with a compound comminuted fracture of radius and ulna. Chloroform having been administered, it was put up as the preceding case, but dressing had to be changed four times in the first three weeks, as patient was very troublesome. Temperature was normal throughout. Dry dressings were discontinued on November 21st. The wounds were all healed by November 29th, when patient was discharged with firm union of bones. He was last seen at the end of December, when the arm was very straight, and all movements unimpaired.

Reviews.

The Commonwealth; a Series of Essays on Health and Felicity for every day readers. By B. W. RICHARDSON, M.D., F.R.S. Longmans, Green, & Co.

DR. RICHARDSON might have taken as the motto of his book a sentence which occurs at the end of it, "We are educating politics, as well as men, by what we teach—an education which, in the present state of dense political darkness, is the noblest work we can possibly execute, until those who rule understand common human nature." Verily, when that which should be light in the common wealth is darkness; how dark is the darkness. This volume consists of twelve essays. It would be hopeless to attempt to present to our readers a *resumé* of their contents, we shall, therefore, confine ourselves to one of the subjects treated of, the education of the young, and let our readers acquire a knowledge of the others from the book itself. The author addresses himself professedly to lay readers; we are of opinion, however, that the information he has to give is quite as much needed by the majority of the members of the medical profession. We select the subject of education, because it is the most potent influence at present at work in determining the destiny of the English people. It is all but universal, and it is, on the whole, uniform in its character, so that it is in fact a huge experiment in physiology made, it must be said, by those who, by their training, are incompetent to attempt it wisely and well. It need, therefore, be no cause of wonder that Dr. Richardson, in common with numbers of other thoughtful men whose scientific training has been such as to give their opinion weight, considers that the Education Act utterly fails to provide a course of instruction suitable to the national requirements. The principal counts in his indictment of the present system are: that in it there is no provision made for the physical development of the pupils; that too long time is spent in intellectual work—three hours a day is all that, in his opinion, children should be required to spend in learning lessons, whereas they are kept at them for six or seven; and that they are not taught those habits of observation and neat handedness which are most necessary for those who are to be hereafter the mechanical workers of the nation. What Dr. Richardson advocates is the half-time system, according to which the children are employed for half their time in learning lessons, and the other half in learning some handicraft. It is a remarkable fact that under this system

children actually make more progress in the acquisition of knowledge than they had previously done when they were occupied double the time at lessons. Dr. Owen Rees, who has had extensive experience in these matters, writes, "The present system of National education produces a dislike and inaptitude for labour among the children of the working classes, which, unless altered, will, I fear, produce very sad results. The sudden change from schoolroom to workshop is the cause of many children being unable to bear the trial they are called upon to undergo, and hence they become idle vagabonds or worse. All the boys admitted into this school are quite unable at first to work, and seem to have had no possible previous training to prepare them for it. It is only after they have for some time enjoyed the advantage of our half-time system that they acquire any willingness to labour."

There is another aspect of the education question which has never received that attention it deserves. Intellectual perversity is not inherent in children in the same way that moral perversity is. That inheritance is a universal one, yet all education is directed to cultivate and inform the understanding, or at least is conventionally supposed to do so, while moral education is entirely neglected. It will no doubt be replied that, except in the schools of Secularists, religious education is given from day to day. But our answer is an appeal to facts. Bad as is the intellectual products of our schools the moral product is still worse. The majority of children leave the schools able to read and write—at least after a fashion—but what proportion through the influence of the schools grow up to be temperate and chaste, honest and truthful? If the country is to be saved from moral dissolution there must be an overturn in the system of teaching. The first thing to be done is to introduce the half-time system, and to make work a means of training to truthfulness and conscientiousness. The boy or girl who has learned to do the unseen side of a piece of work just as well as the one that is seen has got a better lesson in morality than if he had learned to say by rote, "Thou shalt not steal." The next thing is to have the schools so arranged that there shall be room in them for all kinds of wholesome games and amusements in which the children may be occupied under general superintendence. Who has not listened with mingled sorrow and indignation to a group of Board School children at play? The mutual accusations of meanness, cheating and lying, and the violent outbursts of temper which are displayed. The playground could be made a school of moral training of the best kind. Again the Board Schools ought to be utilised in the evenings as places of resort for young people who are passing from school into the businesses of life. The two great preservatives of young people from the snares and temptations of life are total abstinence and a taste for pure reading. This is the testimony of all whose judgment is entitled to weight in the matter. If every Board School was made the centre of a Temperance Guild, and was furnished with a good library, and if the scholars were trained to take the same kind of pride in their school as young men of the educated classes do in their college, and if it always provided a pleasant resort in the evenings, the social problem would be a long way nearer to solution. Young people who had received such a training would be prepared to appreciate the "People's Palaces," which ought to exist in every large city. Finally, Board Schools at which the children of the working classes are taught ought to be provided with

kitchens, in which tasty and toothsome dishes should be prepared by the girls and sold at cost price to the surrounding inhabitants. When public schools become training schools in the arts of domestic life there will be some hope that the future generation will not be so hopelessly incapable as the present. We commend especially to our readers' attention the chapters on *Health and Recreation*, *Health through Education*, *The Poverty of Wealth*, and *Upper and Lower London*. What Upper London is, our readers may guess. It is not the "upper ten." A. W. WALLACE.

The Hospital: a Weekly Institutional Journal of Science, Medicine and Philanthropy. A. P. Watt, 2, Paternoster-square.

To "ding down Tantallon and mak a brig to the Bass," used to be the Scottish mode of expressing the impossible. We had believed that "to make another medical weekly a success" was another, though less epigrammatic way of expressing the same thing; nevertheless "The Hospital" has found a site for itself in Paternoster-square, and has attained, we understand, a circulation of some ten thousand a week. Hospitals and nursing, hygiene and sanitation, are the topics chiefly dealt with, and the papers are written for the instruction of the general public, as well as for giving information to the profession. Most important papers have also appeared on the subject of Poor Law relief, and the best method of dealing with London poverty. Altogether we regard the journal as a note-worthy addition to periodical medical literature, and likely to have a wide-spread influence for good. It has for long been our conviction that the medical profession will never take its proper position in the social fabric until the public have some sound knowledge of the principles on which medical practice is carried on. At present there are so many fools to be answered according to their folly that medical men have become, in many cases, like unto them. None of us but must feel a certain amount of humiliation when we think on what our reputation as skilful doctors often rests. We have got credit where we did nothing towards the cure; we have got blame where it was wholly undeserved; and we have deliberately given opinions, like the Delphian oracle, because we knew that if we spoke out what we believed it would very likely be turned against us at some future time. We therefore hail with pleasure any public instructor who will take in hand the enlightenment of the "swinish multitude" as wisely as "The Hospital" is doing; but the work will never be done thoroughly till instruction in physiology and the principles of health become part of the necessary education of a gentleman, and when a blunder in a question of sanitation is considered more discreditable than making a false quantity in Latin. "The Hospital" has introduced the novelty in medical literature of a serial story running through it. We have heard that one of the earlier ones was of love-making between nurse and house physician, and that the matrons and medical superintendents of several hospitals declared that if it was continued they would banish the journal. Be that as it may, the *thing* goes on, and we know of a model hospital where nurses are strictly forbidden to speak to the residents, but some how or other almost every resident leaves *engaged*. Therein we think the young men show their sense. A good wife is more likely to be met with in the wards of a hospital than on the boards of a ball-room. A. W. WALLACE, M.D.

Outlines of the Grammar of Volapük: the Commercial International Language of the World, arranged for the Use of the Student of Languages, etc. By SAMUEL EADON, M.A., M.D. Bristol: Thatcher; London: Walter Scott.

THE reader will at once ask, "What is Volapük?" In consequence we presume of man's first disobedience, and the fruit of that forbidden tree, we have since spoken in divers tongues. Adam and Eve in the garden conversed in the one language then existing. Volapük is the name given to a new language, framed by a very learned clergyman, named Father Schleyer, of Constance, a distinguished linguist. He has availed himself of his learning, and founded these new words, which are part of the Volapük system. This is not a fancy language or a dream of an enthusiast, Father Schleyer has conquered all the difficulties. His system is now taught in America, France, Germany, Switzerland, Italy, Spain, Portugal, Holland, and Volapükists are now very numerous. Dr. Eadon has taken up the study and warmly advocated it in England, and we shall probably soon hear of its introduction into England on a large scale. To facilitate this Dr. Eadon has issued a small grammar, indeed, the fault is that the grammar is too small, as it only gives an outline of the system. We shall probably have soon another work from his pen, more explanatory and complete, with a Volapük dictionary. We give a few samples of the language:

Good-day, Sir	Glidi Söl.
How are you?	Liko Stadois?
Good-bye	Adyo.
How is your father?	Liko fat olsik Stadom?
Do you study Volapük?	Li Stadols Volapüki.

The grammatical construction of the language appears very simple and can be easily mastered. Volapük is intended to be an international language; to be chiefly used in correspondence; to take the place of Latin amongst the learned and the scientific of all countries. Dr. Eadon says: "Diversity of language is felt to be a great barrier to international intercourse. Volapük, however, is not intended to destroy that diversity, but to supplement it by the introduction of a neutral, or unnational language which the people of all nations may learn, without wounding pride or national jealousy. Its invention was never meant to supersede any present dominant living language, but to be acquired, in addition, to the mother tongue of every people. In these modern times a new order of things has grown up. There are now international congresses, international post-unions, international cables, international canals; and all these, and many more, are in operation, without interfering, in the smallest degree, with the national autonomy of the different nations concerned. So Volapük, an international, but scientifically constructed language, will, in a similar manner, range itself alongside the living languages of the world without interfering with, or affecting injuriously, in any way, their autonomy, or requiring them to pass off, in a sort of lingual 'dim eclipse,' or, perhaps, vanish altogether and be lost from human memory."

Short Notices.

De L'Electricité Comme Agent Therapeutique en Gynecologie.
Par le Dr. F. Mundé, pp. 72. Paris, 1888.

THE author of this treatise is a distinguished obstetrician in New York, where he holds hospital appointments, and

is professor in gynæcology. Under his auspices the work has been translated into French by Dr. Menière, to meet the want of such an essay. "No work on gynæcological electrotherapy," the translator observes, "has yet been published in France," the various treatises on medical electricity, passing over the diseases of women. In this manual it is intended to supply the practitioner with information on the various forms of electrical apparatus, together with the indications for their employment. The most serviceable forms of galvanic and Faradaic apparatus, together with their general method of employment are described. Descriptions of various forms of electrodes are given and accompanied by illustrative drawings. A large share of this work is taken up in enumerating the affections of the female sexual organs in which electricity offers a prospect of successful employment. The use of electricity the author observes is contra-indicated in acute or subacute inflammatory affections of the pelvic organs, but it may be used with advantage in the form of *Faradisation*, in cases of imperfect development of the uterus and ovaries; in amenorrhœa, sub-involution, menorrhagia, uterine displacements, and uterine fibroma. *Galvanisation* is suitable for uterine hyperplasia, chronic inflammations, neuralgia, dysmenorrhœa, etc. The Faradaic current, by its stimulant properties, augments the nutrition and vital functions of these organs; the galvanic current is to be employed where it is required to promote the absorption of adventitious products. Generally, it appears that the pathological conditions in which the action of electricity is most evidently beneficial is where other modes of treatment have failed.

W. B. K.

Digestion and Indigestion. By De Quintin. Leicester: Provincial Medical Journal Office.

ARE we becoming a nation of dyspeptics? We may well ask this question in view of the thousand and one remedies recommended in the advertising pages of the medical and lay press, and of the increasing literature on the subject of indigestion. Another question, if infants are brought up on peptonised and pancreatised foods, if they are not called upon to digest, except artificially, what will be the consequence in another cycle? Disuse of an organ causes atrophy. We leave this question to turn to the pages of the *brochure* before us. It is difficult to condense into fifty-eight pages such a wide subject as digestion and indigestion, but the author has succeeded in bringing together in a small compass a mass of practical suggestions dealing with various conditions of disturbance in the gastric functions to which the generic term indigestion is commonly applied. The pamphlet might be more fitly termed an *aide memoire* to the various affections treated of. Amongst the subjects included in the pamphlet, are vomiting, hæmatemesis, sea sickness, vertigo, dilatation of the stomach, gastritis, gouty, duodenal, strumous and ovarian indigestion, ulcer, cancer of the stomach, gastralgia and stomatitis, all of which are considered from a practical standpoint, the *brochure* being opened by a few sound pages on normal digestion. We note with approval one point—viz., the author's avoidance of recommending patent medicines, and his adherence to the old-fashioned system of prescribing for symptoms. A series of numbered formulæ, sixty-seven altogether, selected with judgment, accompany the pamphlet, and will be welcomed by the reader.

The Provincial Medical Journal,

FEBRUARY, 1888.

OUR American exchanges furnish us with particulars of a very important discussion at the Academy of Medicine, New York, on November 17th, on the subject of "Cardiac Murmurs." The opinions expressed by several speakers will not be absolutely shared by English observers, though there will, we think, be a general agreement that certain cardiac murmurs are without great pathological import, and have been too hastily pronounced of primary importance. Dr. HEINEMANN introduced the debate by asking what constituted a cardiac murmur? and what did it signify? A murmur was defined as an abnormal sound developed in the heart or blood vessels, and the changes in the heart's normal sounds were those of exaggerated intensity, diminished intensity, and duplication; but these changes accompanied not only the normal sounds, but pathological conditions of the heart. He stated that hæmic murmurs were heard at the base as well as the apex, contrary to the view of HAYDEN. Dr. HEINEMANN described the various murmurs heard in health and disease.—Dr. A. L. LOOMIS said that the more one studied cardiac murmurs the less reliance would be placed upon them as positive indications of any cardiac disease which prejudiced life seriously. The murmurs spoken of as friction endocardiac, were not due to friction. Cardiac murmurs were vibrating sounds produced within the blood current. All the true hæmic murmurs were heard as often at the apex as at the base. The great question to be determined was the condition of the cardiac wall. With regard to organic lesions of the heart, when there was stenosis, and also changes which permitted regurgitations, the significance of those murmurs was not determined by their point of maximum intensity, area of diffusion, or by any quality they possessed, but entirely by the amount of cardiac dilation which might be present, the cardiac hypertrophy which might accompany them.—Dr. A. H. SMITH thought the tendency had been to exaggerate the importance of cardiac murmurs *per se*.—Dr. F. S. BURT believed that some cardiac murmurs were so often associated with definite lesions, that they were of great assistance in making a diagnosis. Murmurs existed without cardiac disease, and grave cardiac disease might be present and no murmur produced; but the diagnosis should be made on the history and symptoms, together with the condition of the cardiac muscles.—Dr. FRANCIS DELAFIELD said there had been too many descriptions and too many explanations of cardiac murmurs. It would be very satisfactory if all could have the same idea as to what a cardiac murmur was. His own feeling was that the way to solve the problem was to be as strict as possible, and not to call any sound a murmur unless it was a new sound added to the normal sounds.—Dr. KINNICUTT's experience coincided with that of Dr. LOOMIS with regard to the site of the murmurs of anæmia. He believed they were heard almost as frequently

at the apex as over the pulmonary area; he was convinced that any differential diagnosis between a functional and mitral regurgitant murmur, based upon the dictum laid down in both text books, that the latter alone was conducted to the axilla and the angle of the scapula, must often be incorrect, as the induction of the murmur depended largely upon its intensity. He asked Dr. DELAFIELD if he had any method of distinguishing between a mitral functional and a mitral organic murmur.—Dr. DELAFIELD replied that he knew of no way of distinguishing by the murmur, but was guided altogether by other considerations.—Dr. JACOB thought that diagnosis of chronic heart disease should not be made unless there were changes in the size of the organ, for there were organic sounds which disappeared, and children with adventitious cardiac sounds might get rid of their systolic murmur.—Dr. J. C. PETERS said that he had no doubt that many children were frightened to death by physicians.—Dr. R. C. M. PAGE was satisfied that almost any heart murmur might be heard at almost any part over the chest.

Dr. C. L. DANA gave a new turn to the discussion. He said that one important practical question to be decided was whether these children should be allowed to engage in athletic sports, such as the common sports of school-life and boyhood. So far as his experience went, indulgence in them was beneficial, when regulated by the character of the lesion and the general condition of the patient.

Dr. KINNICUTT said that graduated physical exercise largely entered into the present method of treatment of organic disease of the heart in Germany, and the best results were claimed for it. He personally believed that carefully regulated athletic sports were not contraindicated in many cases.

Dr. DELAFIELD regarded the point made by Dr. LOOMIS concerning the presence of cardiac murmur in children, and the development of serious symptoms when the degenerative period in life was reached, as well taken and one that was true, yet he doubted if that were the entire truth. It seemed to him that the question took a rather wider range than that. It was unquestionably true that children who had had endocarditis did very well for many years, and when they got old cardiac disease developed. On the other hand, it was equally true that a great many developed endocarditis when adults, and went on many years, until they reached the same period in life and then they began to suffer. The same was true of pulmonary emphysema, and also of the atrophic form of chronic Bright's disease. Patients suffering from either of those affections might go on in fairly good health until they reached the same period in life, and then have serious trouble. Did not all this mean that persons who suffer from this particular form of chronic inflammation might, if the inflammation had developed slowly enough, experience no trouble until they reached this hazardous period in life, when the same lesion would cause a great deal of trouble? He was rather disposed to place these

children's cases not by themselves, but regard them as another part of the same general rule.

Dr. A. H. SMITH thought that so long as the muscular exercise could be graded it might answer to allow children with cardiac disease to participate in school sports, but he was unwilling to allow a boy with cardiac insufficiency to take part in rowing matches, etc., where he would be obliged to go through with his duty at all hazards.

The Chairman referred to five men who did well as the result of engaging in the ordinary sports of college, but not rowing matches or violent games.

Dr. KINNICUTT said that by athletic sports he meant the usual outdoor sports of children and youths. He certainly would forbid a patient suffering from organic disease of the heart to engage in the athletic *contests* of the present day.

Dr. HEINEMANN said that the particular point which he wished to reach was an agreement as to what shall constitute a cardiac murmur. He thought it would be agreed to, that only such sounds should be considered as cardiac murmurs as were *adventitious*, and not changed heart-sounds. He then spoke of thrill—the diagnostic value of which he regarded as questionable. He also referred to the case of a long-shoreman, sixty-nine years of age, who carried a murmur fifty-two years without special inconvenience. In the light of such cases the significance of cardiac murmurs must still remain an open question. An important point to be decided was, when shall we say that a given sound is not an accentuation, but a cardiac murmur, and when not a murmur, but an accentuation? He thought it probable that in solving the problem it would become necessary to invoke the aid of the sphygmograph and other instruments of precision.

We have condensed this report from the *New York Medical Journal*. Those of our readers interested in this important subject would do well to obtain a copy of the *Transactions* of the New York Academy of Medicine, and read the report in full.

THE general practitioners may justly exclaim, "Save us from our friends," in view of the scheme now on foot to establish provident institutions in the metropolis. It is time for those who are in general practice to speak out, and in every way resent the action taken by those philanthropists, who in their anxiety for the welfare "of the industrial classes," entirely ignore the interests of the other class who have suffered already, and who will suffer, from the false sentiment which has so long dominated the practice of medicine. It is our duty and privilege to minister to the poor and to the afflicted. We recognise this, but we draw the line. It is not our duty to attend all classes gratuitously, or at unremunerative fees. Our medical charities have been so long abused, and the evils have been so long recognised, that it is late in the day now to dwell upon these abuses, but we are forced to take up this subject by the proposed extension of provident dispensaries in London. Calculations, not contradicted, tell us that a million or so a year receive free medical aid in London.

That represents a noble share in beneficence on the part of the profession. Let us assume that the million are deserving of this help from the profession; we wipe out the loss it represents, hoping that it will be debited to the credit of the London practitioners in the great account book. In what we have to say we hope we shall not be misunderstood. We feel sure that those who have started this scheme have been actuated by the purest motives, and that they really believe they will in this way benefit the general practitioners. We think, however, this is a question on the merits of which general practitioners alone can decide. It is difficult for men in excellent consultant practice, who receive their guinea fees, to understand the mode of livelihood followed by the general practitioner in such a metropolis as London, or in our large towns and cities. Every new provident institution cuts off the source of supply. A few men by an enormous amount of work, under the provident scheme, will be able to earn a bare living, but the bulk of the profession will suffer. If we apply the principle to a small town, we shall see how the provident system will work. In a town like Halifax, of 80,000 inhabitants, there are about thirty medical men; 70,000 probably represent the working classes. A few medical men have the practice amongst the 10,000 rich; the bulk of the profession have to get a living out of the 70,000 operatives. The operatives have good wages, and can pay 2/6 fees. Provident dispensaries at 6d. and 1/-, if started here on the London principle, would utterly ruin the practitioners, who are now able to live in fairly good style on the fees willingly paid by the industrial classes. On this point the almost unanimous opinion of the general practitioners is in favour of our view. The same reasoning may be applied to London. We unhesitatingly condemn the whole scheme, and we hope that the general practitioners of London will be wise in time, and also resist it. We were in favour of provident dispensaries *at first*, because we hoped that they would take the place of the out-patient departments of our hospitals; but so far from doing so, the out-patient departments flourish more strongly than ever, and public and sham provident dispensaries also thrive. What with hospitals, clubs, private dispensaries, public dispensaries, poor-law dispensaries, sham provident dispensaries, from what source is the general practitioner to derive an income? Will the general practitioner allow himself to be swamped in this way? We regret we have to oppose such men as Sir ANDREW CLARKE, Sir SPENCER WELLS, Mr. HOLMES, and others, but we are convinced that they are on the wrong side of the hedge, and we have no respect for "authority as authority."

We venture to assert that the originators of this scheme are beginning at the wrong end, that in place of lowering the fees obtainable by the hardest-worked class of the profession, they should begin by raising the standard of fees amongst that class who are the least worked. What is wanted may be summed up as follows:—The leaders in medicine, as Sir ———, should charge no less than three guineas for a consultation; this would relieve the

impoverished state of the younger consultants, who according to *status* should either charge £2 2s. or £1 1s. Hospital surgeons and physicians in all towns should raise their fees, and should not take less than 5/-; this would enable the younger men to compete with them, and they would be able to obtain 2/6 fees from the industrial classes, who are in as good a position to pay now as at any time during the last twenty-five years. We must make provision for the really poor. That provision amply exists. Moreover, in private practice each medical man can best show his generosity by attending gratuitously any deserving poor he meets with. The most clamorous are not the most deserving. A clerk with 25/- a week, or struggling young professional man, architect, painter, etc., with large families are the most deserving, and such opportunities of doing good fall to the lot of most of us. It is for these classes we have the fullest sympathy, because they hide their claims for consideration. The reforms needed should proceed on these lines, and not in the lowering direction. The general practitioners have the matter in their own hands. If they are content with the scheme, then there is nothing more to be said.

“How am I to distinguish the skilled from the unskilled man? I have no means of judging; all doctors seem alike to me. If a man calls himself ‘doctor,’ I am bound to believe him. I was under the belief that the Government did not permit any man to practise who was not qualified?” This was the remark addressed to us the other day by a patient who was disgusted to find that in an emergency he had called in an individual who, known as “Dr.,” actually possessed no qualification whatever. An article in our January number, on “The Medical Man of the Future,” bewailed the increasing higher general culture of medical men, and the miserable pittance which in practice they are compelled to accept. It is true enough that medical men are inadequately paid as a rule, but who are more to be blamed than themselves for such a state of affairs. The article in question alluded to improved sanitation as diminishing sickness, to increase of popular medical literature, to increased sale—and facilities for sale—of patent medicines; these may certainly have some influence in reducing work and income, but it cannot be pleaded that they *lower fees*. Who can be supposed to look after the interests of a profession which will persistently neglect to do so for itself. The apathy of the medical profession in matters of presumably the most vital interest is almost incredible. With abuses bristling all around, they sit still and grumble, but when asked to co-operate with others to obtain redress or reform, they take no notice. A kind of unwritten law exists, entitled, “The Etiquette of the Profession,” but how is it carried out? Where is the tribunal to decide whether it has been infringed or not? There is no acknowledged judicial body to deal with such a matter. In the sister professions of divinity and law, offenders are called in question directly, but in medicine, except for the occasional

expression of opinions of anonymous correspondents in a few medical journals, there is nothing at all approaching a legislative body. There is a General Medical Council, but so far as any participation in the practical every-day life of the practitioner is concerned, it might as well not exist. The exigencies of the profession necessitate competition to such an extent, and of such a character, that unanimity is destroyed. The practice of bribing (for it is nothing else) patients to come by charging less than one’s neighbours is largely on the increase; it smacks very much of the pernicious trading habit of underselling. The existence of such a practice simply places etiquette on the shelf, and, as a matter of experience, when any breach of etiquette is complained of, it will be found in the majority of cases to be merely an example of what an American author pithily describes as “the golden rule applied to others.” Unqualified practice abounds, and is increasing, but no steps are taken to deal with it. Quite apart from any bearing on the welfare of the medical profession, this, as we have formerly pointed out, is a social evil, as the health of the nation is concerned by it. If such high qualifications and extensive training are required to render a man legally capable of treating disease, how can unqualified men do the same thing successfully? Either medical education and legal qualifications are a necessity or a farce. It is true that the sale and advertising of patent nostrums is on the increase, but what is this but a deliberate fraud sanctioned by the Government? Let anyone read the puffing and extravagant laudation in our public press day after day of quack medicines, with such headings as “Doctors set at defiance;” “After six doctors failed to cure,” and so on, and ask themselves the question whether this is not showering contempt upon the profession. Let none imagine that such things can be overlooked as harmless; they are begetting the idea that the medical profession is merely pretentious. People who read such things day by day believe them, because they are allowed to go unchecked. They think that as there is a “Medical Council,” which does not interfere in such cases, therefore they are sanctioned by that Council. It is a natural inference which cannot be avoided under present circumstances. How are such things to be prevented? Easily, we reply: let the profession combine to make their views, desires, and wrongs known—to exert pressure on the Medical Council—to support parliamentary action—to make the Government aware of the true state of the case, and the remedy will be soon forthcoming and that effectively. But unless the profession awake to the necessity of doing something for themselves, they will day by day get into a worse position, and sink to a state of less importance in the eyes of people than they even now occupy.

No FACT has ever been more clearly proved, beyond the possibility of doubt, than the effectual prevention of small-pox by vaccination. To urge that in many cases small-pox has occurred subsequent to vaccination, goes

for nothing, as this is at once met by the assertion that the vaccination was imperfect, or most probably made with inert lymph. With compulsory vaccination on the Statute Book, it seems a most extraordinary thing that small-pox should ever occur in this country, yet for at least ten years it has been constantly present with us, sporadic in occurrence, rising and falling; sometimes approaching an epidemic character; at others limited to a case here and there; still it has never been absent. At Sheffield, during the last few months, an epidemic of a serious character has occurred, and is extending. Again, the whole question of the value of vaccination will be raised, and freely discussed. Attempts will be made to inflame the popular mind by ignorant demagogues and sentimentalists; every dereliction will be dragged to the front; every result of want of care adduced as a statement of absolute fault; every consequence of failure to enforce the law paraded as a failure of the efficacy of vaccination. What such antagonists rely upon chiefly is the allegation that notwithstanding "Compulsory Vaccination," small-pox keeps recurring; and they point to the occurrence of small-pox in innumerable cases where some form of vaccination has been practised. We use the phrase "some form" advisedly, because it will be found that in such cases the vaccination has not been thorough and complete; that is to say, whereas proper vaccination will prevent the inception and development of the small-pox contagion, any *failure in the quality of the lymph* employed will not produce the immunity desired, notwithstanding that it may be followed by the production of a well-developed and apparently normal pustule. Vaccination, in its proper or strict signification, means the introduction into the human system of the lymph obtained from the pustule of vaccinia or cow-pox, and this was Jenner's practice; but it came to be assumed that because—notwithstanding after passing through various human systems successively—the lymph continued to produce a good pustule, its protecting power remained unaltered. That this view was correct is more than doubtful, as it seems only reasonable that the vaccine poison should, by this passage through, and contact with, so many human constitutions, become to some degree modified in character, and not improbably changed altogether in its nature. Certain it is that in all those cases where, subsequent to vaccination, small-pox has occurred either in a modified or full degree, investigation, where it could be made, has elicited that the vaccine lymph originally employed has been humanised; while observation, especially since the epidemic which traversed the whole country in 1870, has proved that the lymph used, as was frequently done, from secondary or re-vaccinated cases, was found to have wholly lost its protective character, notwithstanding that in such cases it might have been taken from a primary human source. It is only fair to conclude then, if vaccine matter from secondary cases becomes thus deprived of all specific protective power, that even after passing through a primary case, it must inevitably lose to some degree its full antagonising power. Accepting this

view, it can very easily be understood why in so many cases where vaccination had been apparently well done, so many instances of the occurrence of small-pox should have been observed. On the other hand, in no instance can the occurrence of small-pox be pointed out after the successful use of pure and unmodified calf-lymph, more especially in cases where it has been used for re-vaccination. A further strong point urged by the opponents of vaccination, and one to which we feel compelled to give attention, is that lymph, however pure in its source, acquires by its passage through the human system a human character, and becomes imbued with any constitutional tendencies which may be present, and so liable on its introduction into another human organisation to import these tendencies, which may be those of serious morbid conditions, and more especially of affections such as tuberculosis, syphilis, and other ailments having a specific character. Many facts have been adduced to support this serious charge, which it is difficult, indeed almost impossible, to set aside. Be its correctness as it may, it has sunk deep into the popular mind, and with an increasing tendency on the part of the population to resist compulsory vaccination, the Government will soon find themselves face to face with the alternatives of either enforcing the Vaccination Act, or letting it fall into abeyance. That the latter should be the course adopted, will never be the case, we feel certain; common sense and experience are against it, and therefore it will be necessary to render the enactment more stringent in its provisions. But in doing this it will be only right that every presumed or probable cause of objection should be removed. While on one hand the rational portion of the community have a right to insist on the enforcement of the Act, on the ground of objection to permitting any person to constitute himself or his family a focus of such a dangerous malady by non-compliance with a just enactment; on the other, the objectors have a right to demand that if their children must be vaccinated, they should have only pure lymph used, free from any human contamination or chance of introducing disease to presumably-healthy constitutions. To do this there is only one course open—namely, to forbid vaccination with any but pure calf lymph, to abolish all arm-to-arm vaccination, and to inflict an exemplary punishment for non-compliance. Were this made the law, we feel convinced we should hear no more of opposition to such a salutary and wise statute. We feel bound to observe that the existing mode of public vaccination calls for strict investigation, efficient superintendence, and wide reform. In too many instances there is gross carelessness in the selection of cases from which lymph is taken to vaccinate others—and in saying this we cast no reflection on our public vaccinators as a body; only it must be remembered that if but two or three per thousand of them are culpably careless and negligent, the results may be sufficiently disastrous to lend justification to an agitation which, if it should succeed to such an extent as to lead to any abrogation of, or evasion of such a beneficial Act, would be nothing less than a deplorable national calamity.

Annotations.

"Forsan et hæc olim meminisse juvabit."

OUR CONTRIBUTORS, 1888.

WE publish in this issue Dr. Steavenson's first contribution on the subject of "Electro-Therapeutics," a form of treatment rapidly coming into use, and one which the general practitioner can find a legitimate use for. Dr. Steavenson aims at making his papers practical. Amongst many contributions promised we may particularly allude to the following:—"On the Treatment of Sterility," by T. More Madden, M.D., etc. "A Year's Work at the Samaritan Hospital," by Geo. Granville Bantock, M.D. "Some Notes on the Management of certain Uterine Cases," by Gordon Black, M.D. "On the Etiology of the Pathological Conditions in Women, which have their Origin in the Pelvis," by John F. Le Page, M.D. "Obstruction of the Common Gall Duct, and difficulties in its Diagnosis," by Andrew Scott Myrtle, M.D. "Obscure Cases of Cancer," by J. A. Myrtle, M.B. "On New Surgical Appliances," by Dr. Ward Cousins. "Pine Baths and Inhalations as Adjuncts to Climatic Treatment of Laryngeal Diseases at Bournemouth," by Lennox Browne, F.R.C.S. "Diphtheria in the Puerperal State, and Infants," by H. Alderson, M.D. "On Orthopædic Subjects," by Robert Jones, M.R.C.S. (Liverpool). "The Treatment of Fractures of the Patella," with illustrations, by Hugh Owen Thomas (Liverpool). "On the Eye as an Optical Instrument," by James Rose, F.R.C.S. "Ophthalmic Notes," by Charles Lee, F.R.C.S. (Liverpool). "Diseases of Children," by Charles Macalister. "Infanticide," by Francis Vacher, F.R.C.S. "Ovariectomy in Aged People," by Fancourt Barnes, M.D. "On Retroversion of the Uterus as a Cause of Retention," by W. D. Spanton, Esq. "The Varieties of Gastrodynia," by Robert Saundby, M.D. "On the Utility of Massage," by W. R. Thomas, M.D. (Sheffield).

We are also promised original papers by Herbert Page, M.A., M.D., London; Dr. E. Aust. Lawrence, Lecturer in Obstetrics and Gynæcology at the Bristol School of Medicine; Dr. G. Oliver (Harrogate), Mr. Lawson Tait, Mr. Oliver Pemberton, Dr. Barr (Liverpool), Mr. George Buckston Browne, Dr. Charles Phillips, etc., etc.

TO OUR ADVERTISERS.

"THE mere number circulated of a journal is not the only, nor always the best, test that should guide an advertiser. Some journals, owing to the peculiar character of their circulation, would be far more profitable to an advertiser with a circulation of one thousand, than others with a circulation of ten thousand. This is particularly the case with class journals."—"Sell's Dictionary of the World's Press." To this we would add that for journals like the *Provincial Medical Journal*, the circulation is much larger than the number printed; as copies are handed from one to another,

exchanged, and otherwise made to do duty several times over, so that we can almost promise our advertisers *20,000 readers each month*, as this journal is read by at least five medical men for each copy issued.

THE DANGER OF MONEY.

WE are often told that money is the root of all evil, but most people are willing to run the risk so long as they obtain the root. Money may become a means of spreading disease, though few people attach much importance to this danger. Dirty coppers, which have come through hands not of the cleanest, are taken up by dainty fingers; silver and gold which have passed through hands affected with small-pox, scarlatina, syphilis, are exchanged from one to another, without any thought, or even fear of infection. Paper notes, dirty, soiled, crumbled, and even foul smelling are readily taken in exchange. Few people would think of washing coppers, silver, gold, but that such a course of treatment is necessary there cannot be a doubt. We have lately had attention directed to the danger of books from free libraries, but this is infinitesimal with the possibilities of infection opened out by our coinage. Dr. E. Miller Reid (*Med. Reg.*) thus graphically describes the danger:—"Money leaves the press or the mint, pure and undefiled, to become a nidus of infection and a colporteur of disease. It leaves the desquamating hand of the scarlatinal patient to go to the hand or mouth of the healthy child. It is taken from beneath the pillow of the variolous sick and given to the unsuspecting merchant, mechanic, and labourer, or innocent lawyer. It is cut from the rags of the leprous beggar, to find its way into the pocket of a member of the Legislature, or a minister of the Gospel. It goes from the foul bootlegs of thieves and burglars, to be carried by the timid cashier to Canada. I have seen it in the hands from which was dripping the infectious discharge of a blennorrhœa, and have shivered as I have thought that in a short space of time, that same note or coin might be pressed to the cheeks, lips, mouth, or eyes of some pure girl or woman, whose very purity would render her but the more susceptible of the contamination. I have seen it passed into circulation from the sick-room, by fingers that had just been removed from a specific sore, and when an hour or so after, I saw a thoughtless lady put a note into her mouth while she buttoned her glove, I should not wonder if it might not be similarly polluted. It is taken from the infected bosom and stockinged limb of the magdalen to be carried within the gloves on the clean palms of our mothers, daughters, and wives. It is the travelling companion of Asiatic cholera, and a sojourner with Yellow Jack. I will not speak at length of its odour; it is sufficient to mention that that it has enabled mail robbers to discover the presence of money in letters. No one who has a cut or abrasion is safe in letting a note or coin come in contact therewith. Let any doubter of this assertion be answered by the spirit of the bank official who lost his life in consequence of disease contracted by moistening his fingers at his mouth while counting bank-notes."

THE HENDON COW DISEASE.

PROFESSOR CROOKSHANK introduced an important communication to the Pathological Society at the meeting of the 15th December. It will be in the memory of our readers that considerable alarm was excited some months back by a report presented to the Local Government Board, "on certain observed relations between scarlatina in various districts of London, and milk supplied from a dairy farm at Hendon." Mr. Power and Dr. Klein were deputed to make enquiry into the matter. The results of their enquiries have been brought before the public in the Fifteenth Annual Report of the Local Government Board, and in the pages of the medical journals. These results were sufficiently alarming, but not presenting an absolutely definite conclusion, they have been further investigated by Professor Crookshank, whose conclusions have relieved them of much of their dangerous characters. Dr Klein states that by inoculation of matter from the sores of an affected cow, a positive result was obtained in four calves, the inoculated places having become sores, showing vesicles and forming scabs. By cultivation a strepto-coccus was obtained, identical with the virus of the cow disease. Further, that by subcutaneous injection of the strepto-coccus a general disease was produced, *bearing in many respects a close resemblance to human scarlatina* (the italics are ours). "Furthermore," Dr. Klein observes, "as respects the concern that cow's milk may have in the communication of disease . . . it would seem that the pure milk does not contain the organism, but that the milk during the act of milking is pretty sure to become contaminated by the fingers of the milker bringing down into the milk particles from the ulceration on the teat. The organism contained in these particles would find in the milk a good medium in which to multiply." So far, however, as the spread of scarlatina by the cow disease is concerned, we may divest our minds of fears on this score after a perusal of the report of the examinations by Dr. Crookshank. The careful study of Dr. Klein's descriptions of the disease, and comparison of these with those of Dr. Crookshank, will go far to show that there is every reason to believe that an erroneous conclusion has been arrived at by Mr. Power and Dr. Klein, highly valuable as are their bacteriological illustrations of the affection amongst cows.

The Hendon cow disease, brought before the meeting of the Pathological Society, on December 17th, 1887, is placed in a different light from which it is regarded in the Report of the Local Government Board. Dr. Crookshank, shows that it has all the characters of vaccinia, and some of those of scarlatina; while there was an absence of the latter disease among the consumers of the milk on the farm, in the village, and in the neighbouring town, numbering all together about fifteen hundred or two thousand individuals, one hundred and sixty animals having contracted the disease. There was no epidemic in the town district where the milk was distributed. Dr. Crookshank was able to examine the case of a boy, whose face at once confirmed his suspicions

that the disease of the tests of the cattle was the true Jennerian cow-pox. On further enquiry he met with numerous instances of the communication of the disease from the teats of the cows to the hands of the milkers. The occurrence of scarlatina in London at the time must, therefore, be regarded simply as a coincidence, its course being unknown. The cultivations performed by Dr. Crookshank having yielded results similar to those by Dr. Klein, there remains the inference that a strepto-coccus, capable of setting up septic inflammation, occurs in scarlet fever, diphtheria, puerperal fever, improperly preserved milk, and perhaps foot-and-mouth disease, in scarlatina, and other febrile diseases. We have herein placed before our readers a probable solution of the fallacies and fears that beset the supposed extension of scarlatina by milk. The practical outcome of Dr. Crookshank's remarks is that prompt measures should be enforced for isolating diseased animals, to prevent the spread of disease.

THE CROWN PRINCE AND HIS CONSULTANTS.

SIR JAMES PAGET in a lecture on "Dissection Poisons," said: "Sir William Lawrence used to say that he had not known anyone recover on whose case more than seven had been consulted. Our art has improved. I had the happiness of being attended by ten—Sir Thomas Watson, Sir George Burrows, Sir William Jenner, Sir W. Gull, Dr. Andrew, Dr. Gee, Mr. Cæsar Hawkins, Mr. Savory, Mr. Thomas Smith, and Mr. Karkeel. In this multitude of counsellors was safety." Sir James Paget was fortunate no doubt in having consultants who were all agreed on a course of treatment. The Crown Prince, on the other hand, as far as we can gather from the medical journals, had as many consultants who illustrated the truth of the adage, *tot homines, tot sententiæ*. Fortunately, he had the wisdom to trust to one adviser, and so far time has justified Sir Morell Mackenzie's course of treatment.

SMALL-POX IN THE PROVINCES.

SEVERAL of our provincial towns are filled with small-pox patients, and several others have only escaped through the vigilance of the sanitary authorities. Tramps have been the means of spreading the disease from one town to another. At Halifax on December 29th a tramp arrived from Hebden Bridge covered with small-pox eruption. He was fortunately within a couple of hours placed in the Small-Pox Hospital; otherwise he might have set up an epidemic. Another arrived at Halifax on the 20th, and was taken to the Workhouse suffering from rheumatism. On December 30th the small-pox eruption appeared. He had come from Leeds. Both cases are now well, and the only ones that have been in the borough. At the present time there is every opportunity of trying the application of a solution of sulphide of calcium to mature the eruption, and to give ease. We have used the remedy in several cases with benefit. The first case above mentioned was a severe one of confluent small-pox. The face was swollen; the

eyes closed. The face and body were painted with the golden lotion known as liq. sulph. cal. (the specific for scabies), weakened with water 1 to 2. The remedy was effective. The pustules shrivelled up, the face settled down, and the man was soon able to open his eyelids. We believe it may be applied in any stage of the disease; this has yet to be tested. As regards tramps, it is a matter of regret that the Local Government Board cannot issue an order, "detaining all tramps, found in workhouses on a certain day, for three months."

BOLSTERING UP THE SYSTEM PASTEUR.

"WHAT is truth," saith jesting Pilate, and waited for an answer. We may ask the same question when we read such evidence as the following in the *British Medical Journal*, December 31st, 1887, p. 1445:—

"In all, or nearly all, those fatal cases where Pasteur's anti-rabic treatment has been pursued, the patients had allowed a week or longer to elapse between the occurrence of the bite of the *rabid animal* and the commencement of the inoculative treatment."

Who could have written such a paragraph in the face of the evidence furnished by the Institute itself! Look at the following failures:—

Jammot bitten	Aug. 3rd.	Treated	Aug. 4th.	Died	Sept. 24th.
Saulat	July 9th.	"	July 9th.	"	Aug. 4th.
Marchois	July 3rd.	"	July 5th.	"	Aug. 16th.
Penichaud	June 12th	"	June 14th.	"	Aug. 19th.
Gerard	Dec. 1st.	"	Dec. 3rd.	"	Jan. 3rd.
Rouget	Oct. 20th.	"	Oct. 20th.	"	Nov. 26th.

We could extend this list, but one failure is as good as 100; it proves the powerlessness of the remedy. But why is the week's delay accountable? If the inoculations rested on a true scientific basis, they should be powerful at any time before the development of hydrophobia. Let that pass, and let us examine another paragraph:—

"It is worthy of notice that *nearly* every European country now has an anti-rabic institute except our own."

This is very surprising news. Is not Germany in Europe? Has it a Pasteur institute? Has Belgium? Are not both these countries in the foremost ranks of medicine? We are sure Mr. Hart has either not seen these two paragraphs, or he has trusted this section to a too enthusiastic partisan of the method, to whom "facts" are of little value in comparison with bolstering up the system Pasteur.

SANITARY UNDERCLOTHING.

MEDICAL men are agreed on the advantage of wearing pure woollen underclothing, this form of apparel being particularly recommended for children, and for all ages. English manufacturers in the North of England have for years been making various articles of apparel of pure wool, and in economical households thrifty housewives have worked for their children underclothing of pure white wool. In Yorkshire we know that this has been the case. From motives of economy, or for other reasons, what are termed mixture yarns are frequently used, and where these mixture yarns are made entirely from white and natural grey wool, no harm can ensue; but dyed wools are often substituted, even dyed grey, to look natural. These dyes are frequently

made of cheap material, and cannot but be regarded as highly injurious. Many other methods of cheapening the manufacture of under garments have been adopted, as in these days competition is keen, and profits low, but the best manufacturers turn out pure articles still. For the reasons given above we strongly recommend the use of garments made from the white wool *only*, in place of the so-called mixture, or *natural grey* wool. It is a fallacy to suppose there is any virtue in wool or manufactured articles imported from abroad. In the present state of English commerce it is the duty of medical men to encourage home produce, always provided that as good an article can be obtained at the same price.

HEALTH SAVING.

IN our last issue we published a notable letter from the pen of a working man who has evidently been thinking. In it he describes very forcibly—what, indeed, is too well known already—the way in which the selfishness, ignorance, and cupidity of some employers lead to operatives having to pursue their work under conditions most injurious to health. Now we wish to place before working men the only way in which they can remedy this state of things, for in their own hands the remedy lies. The artisans and working men of England far out-number all the other parliamentary electors, and it only requires that they should unite in order to sweep from the land every oppression under which they labour. But in order to do this they must fulfil certain conditions. First, they must learn to practice self-denial. It may seem strange for the comparatively well-to-do to preach self-denial to men whose whole life seems to be one long mortification. But it is not so. Working men are very often employer-denied, and society-denied; they are often stinted of their rights, but few of them indeed are self-denied. They have not learnt to hold by the Right against their worser self. They spend what in the aggregate amounts to an enormous sum annually on low and debasing pleasures. If a man is to enter on a kingdom of any kind, the fundamental law of the succession is that he must deny himself. Secondly, working men must educate themselves. The writer of that article is educated in a very true sense, although he did not get his education in the schools, nor, we suspect, in Mechanics Institutes either. Wherever such men exist they should unite and seek to educate others. At present working men are largely ignorant of what will most promote their own interests. Let them work out this problem for themselves. The editor of the *Century* magazine states that the curse of American politics is that the wire-pullers devote all their energies to secure the votes of the worst classes of society, the saloon-keepers and their clients, and therefore select their candidates for this purpose, sure that if they can get a man that will please the rabble, the decent people will vote for him to support their party. This condition of things exists in England too, and what politics need at present is a strong phalanx of the working classes who will stand for the practice of righteousness.

THE LEICESTER DISPENSARY.

THE *Leicester Journal*, January 15th, publishes a long account of a meeting held to suppress and correct abuses in connection with the Provident Dispensary in that town. We give a portion of the indictment, and ask, can such things be? The Rev. A. A. Isaacs said:—"Many of them knew what methylated spirits meant. It was a noxious preparation, and was made noxious because it was admitted free of duty in order to meet the wants of trade, and was sold at 2s. 6d. a gallon. It was utterly unfit to be taken inwardly; but what would they think when he told them that that preparation had been used in the preparation of tinctures at the Dispensary? That was a matter affecting the health of the community. It was communicated to the officials at Somerset House, and one of them was sent down to investigate it; and he (Mr. Isaacs) had evidence that, whilst that official was engaged in controversy, someone on the premises was turning down the sink the tinctures and the preparations which had been made up in the manner he indicated. Mr. Isaacs went on to state that quassia, in a decomposed state, had been sent to the branch dispensaries, and used there, and that he had been told that the rate of payment for the drugs at the Dispensary was the same for 100 bottles as it was for one bottle." The Dispensary is evidently in need of reform. The manager appears, from the report, to have absolute control, and to order matters just as he pleases. The press of Leicester has done its duty well in publishing this full report, and we hope that it will not allow the matter to drop.

THE DANGERS OF OCCUPYING NEWLY-BUILT HOUSES.

ACCORDING to *Medical News*, the town of Basle, Switzerland, has adopted a regulation which prevents newly-built houses from being inhabited until four months after their completion. According to Pettenkofer's estimate, the walls of a building in which 100,000 bricks are used, will require almost 10,000 gallons of water in the construction, which must be expelled before the house becomes habitated. This large quantity of water is used in the pores and spaces of the bricks and mortar until dispelled in the form of vapour. It is a matter of every-day observation that people recklessly occupy houses almost before completion, without regard to their dryness, or other conditions of fitness for occupation.

HOW NOT TO TREAT HYDROPHOBIA.

Dr. Dulles, Philadelphia, says in reference to a case of so called hydrophobia, where the patient was exposed for a quarter of an hour on a chair in full view of a number of students:—"We warn our readers that they need never expect to cure a patient supposed to have hydrophobia if they watch him closely, expose him at a public clinic, offer him water, inject morphine and chloral into him, and above all if they add the administration of curare to these measures. What share in his death is to be attributed to the treatment he received, it would be hard to say. A careful study of the literature of hydrophobia shows that

morphia, chloral, and curare, are useless, and probably dangerous, given as they usually are." Dr. Dulles is severe in his remarks, but we certainly agree with him that the exposure of a patient suffering from hydrophobia in view of a whole class is not the way to benefit a patient.

THE DURATION OF LIFE IN MODERATE DRINKERS.

ACCORDING to the *Medical and Surgical Reporter*, Philadelphia, the great insurance companies of Great Britain have pronounced the teetotalers longer lived than even those who make a moderate use of spiritous liquors. The companies have for a series of years kept separate registers of all their members, the total abstainers being classed apart from the moderate drinkers. From the records they find the records in respect to longevity decidedly in favour of the teetotaler. One of the largest and oldest of these companies, which has kept separate registers for twenty years, declares that among the strictly abstaining class the real mortality has fallen short by thirty-six per cent. of the ordinary expectancy, while fully nine-nine per cent. of the moderate drinkers have attained this expectancy. Mr. Caine, M.P., concludes from a study of statistics, that the total abstainers have an average duration of life exceeding by six years that of moderate users of even the lighter alcoholic beverages, such as wine and beer. We commend to our readers the paper by Dr. George Harley on "Nipping," published in our January number.

New Materia Medica.

Geranium maculatum.—Although this is not, strictly speaking, a new remedy, yet it is new in the same sense as *Convallaria majalis*. It is an old remedy which was used more than sixty years ago in the United States by Dr. Barton, who considered it entitled to the attention of every American physician. Dr. J. V. Shoemaker, Professor of Dermatology in the Medico-Chirurgical College of Philadelphia, now directs the attention of the medical profession to the value of the drug (*The Medical Bulletin*, p. 362) as an astringent in many cases where ordinary remedies fail to be of service. The rhizome of this plant is the part used in medicine.

Geranium maculatum is a perennial herb, common in rich woods in Canada and the United States, and flowering from April to July. It has hairy leaves, which when old become blotched with white (hence its specific name). The flowers are of a light purple colour. The rhizome is collected for medical use in late summer or autumn. It is two to three inches long, and a quarter to half an inch in diameter, tuberculated and longitudinally wrinkled. Externally, it is of a dark brown colour, and internally pale red-brown. There is a circle of small, yellowish, wedge-shaped, woody bundles near the root-bark, the bundles being separated by broad medullary rays. The taste is strongly astringent, but the rhizome is without any distinctive odour. It contains mucilage and starch, and about 13 to 17 per cent. of tannin, gallic acid, and various resins and oleoresins, which have not yet been studied. The latter are considered by Dr. Shoemaker to enhance the usefulness of the drug, and to render it more potent than either tannic or gallic acid alone. In all forms of hæmorrhage, whether internal or external, it is, he states, without a superior. In doses of one drachm of the fluid extract hæmoptysis can be promptly arrested, if a dose is given hourly, and relapses prevented by continuing the medicine at intervals for three or four days. Hæmatemesis may be effectually controlled after ergot, sulphuric acid, iron, ice, and other styptics have failed. In hæmorrhage

from the kidneys and intestinal canal, smaller doses of twenty drops four times daily, for an extended period, answer better. Epistaxis may be speedily checked by plugging the nostrils with cotton dipped in a solution composed of one part of the fluid extract of geranium and three parts of water, or by syringing the nose with the same solution. Bleeding from the extraction of a tooth is easily arrested by filling the socket with a piece of cotton saturated with the undiluted extract, and applying firm pressure for a few minutes. Geranium is also found to be valuable in purpura, scurvy, hæmatidrosis, and the hæmorrhagic diathesis. In diarrhœa of typhoid fever, infantile diarrhœa, and colliquative and chronic diarrhœa, it has proved very serviceable, as well as in chronic dysentery. In phthisis it seems to be of especial value, restraining the diarrhœa, preventing hæmorrhage, moderating fever and night sweats, lessening the cough, and promoting the appetite. In chronic gastric catarrh, and the various stomach disorders due to alcoholic indulgence, benefit is derived from the use of geranium. Diluted with eight parts of water, the fluid extract forms an effective gargle in relaxation of the uvula and fauces, and chronic pharyngeal catarrh, and answers equally well for post-nasal catarrh when applied with a nasal syringe. In the form of injection it can be used in chronic gonorrhœa, leucorrhœa, prostatorrhœa, every second or third day, one part of the fluid extract being diluted with ten parts of water. The pain and irritation caused by fissure of the anus is relieved immediately by touching the fissure with the undiluted extract, and a permanent cure effected by continuing the applications two or three times daily for a few days. For prolapsus ani the fluid extract should be brushed daily over the protruding mucous membrane, and a 25 per cent. solution be injected into the rectum every second day. Repeated applications of the fluid extract will also relieve the irritation of hæmorrhoids, and frequently cause the tumour to shrivel up and disappear. It also relieves the pain of fissured nipples, and forms a protective covering under which healing goes on. A 10 per cent. solution forms a useful application to granular lids, in chronic conjunctivitis and corneal ulceration. In diseases of the skin in which secretion is excessive, such as hyperidrosis and bromidrosis, bathing the parts affected with a 30 per cent. solution of the fluid extract proves effective in lessening perspiration and removing fœtor. Dr. Shoemaker recommends it in the form of a lotion in vesicular and purulent eczema, impetigo, pemphigus, intertrigo, and in eczema and herpes of the genital organs. It is also efficacious in preventing the formation of bed-sores, and promoting the healing of indolent ulcers. It forms an excellent application to cuts and bleeding wounds, for which purpose a small piece of cotton-wool, soaked in the fluid extract, is applied with pressure. In fact, Dr. Shoemaker considers it the best vegetable styptic in the materia medica.

New Remedies.

Pilocarpine appears to have received some attention as a remedy in yellow fever. Dr. E. Hebersmith, in the *Med. Bulletin* (p. 337) reports in detail several cases in which the subcutaneous injection of one quarter of a grain of the hydrochlorate effected the cure of the disease. He is so satisfied of its value that he remarks that if pilocarpine is as effectual in the hands of others as it has been in his, "yellow fever has become a trifling matter."

Ephedrine, the mydriatic alkaloid mentioned last month (p. 32), is reported by Professor Nagen, of Tokio to be useful in cases where atropine is contra-indicated. The strength used is a 10 per cent. solution. He speaks of the hydrochlorate as occurring in acicular crystals, of its being freely soluble in water, and of the solution being unaffected by light. It seems rather remarkable that the occurrence of a mydriatic property has not been noticed before in this genus. If the discovery be confirmed by independent experiments, it lends some probability to the theory that the soma plant of the ancients was a species of ephedra.

Strophanthin has formed the subject of further research by Messrs. Adrian and Bardet. These chemists find that it is a glucoside which breaks up into glucose, and an alkaloid that is probably the strophanthidine of other authors. They are disposed to think, however, that the alkaloid present in the liquid obtained by macerating crushed strophanthus seed in water is not strophanthidine, but that it is probably either related to or identical with the ineine of M. Hardy.

Iodine trichloride is now brought forward as a disinfectant and germicide. It is prepared most conveniently by passing a full current of chlorine into a three-necked flask, into which iodine is vapourised from a small retort fitted to the central neck. The trichloride forms orange-yellow crystals, which are darker if contaminated with the liquid monochloride. This compound is rather freely soluble in water, forming a strongly acid, yellow liquid, with a somewhat penetrating pungent odour. Although soluble also in ether and alcohol, the alcoholic solution undergoes change, even in the cold, chloral being formed. Strong aqueous solutions keep better than dilute preparations, the latter undergoing decomposition, especially when subjected to direct light, hydrochloric and iodic acids being formed, as well as monochloride of iodine. Professor von Langenbuch reports that its germicidal action far exceeds that of carbolic acid, and comes nearer to that of corrosive sublimate, over which it possesses the advantage of being relatively non-poisonous. He considers an aqueous solution of the trichloride of iodine of the strength of 1 in 1,000, or 1 in 1,500, as equal to a 4 per cent. carbolic acid solution, or a 1 in 1,000 or 2,000 sublimate solution, for the disinfection of wounds, the hands, or instruments. A solution of 1 in 1,200 is recommended as an injection for gonorrhœa, or taken internally in the dose of a teaspoonful every two hours as a remedy for dyspepsia, dependent on the presence of bacteria in the stomach or intestines.

Sozoiodol is the name given to another iodine compound which has recently been introduced in the treatment of certain skin diseases by Dr. Lassar. It is stated to be an acid sodium salt of iod-paraphenol-sulphuric acid. It occurs in the form of a white, shining, crystalline powder, which does not melt on being heated to 200° C. It is quite odourless, has a faintly acid taste, and is soluble in water to the extent of 7 per cent., but is more soluble in hot water. It is also more soluble in hot alcohol than in cold.

Guaiacol has been suggested for use in phthisis instead of commercial creasote, on the ground that the former is a more definite body. Ordinary beech-tar creasote contains about 60 to 90 per cent. of guaiacol. When pure, it forms a clear refractive liquid, of an agreeable aromatic odour, boiling at 200° C., and having a sp. gr. of 1.1171 at 13° C. It dissolves in caustic alkalies, and gives with ferric chloride an emerald green colour. It darkens readily when exposed to light, and should therefore be kept in the dark.

Sodium fluosilicate, lately introduced as an antiseptic, is recommended in the *British Medical Journal* (p. 1376) by Mr. T. E. Hayward, as an equally effective and safe substitute for corrosive sublimate in midwifery practice. It is only slightly soluble in water, a pint of water dissolving about fifty grains. A saturated solution should be used. It is easily carried in the form of fifty grain powders.

A new use of glycerine is pointed out by Dr. J. Althaus. A teaspoonful or half a teaspoonful injected into the rectum by means of an ordinary glass syringe causes a speedy evacuation without pain or irritation. Dr. Althaus has found this simple remedial means to act well in cases of habitual constipation. He explains its action as follows:—Glycerine, when brought into contact with mucous membrane of the rectum, withdraws water from it, causing hyperæmia and irritation of the sentient nerves of the rectum, which lead by reflex action to powerful peristaltic contractions, ending in defæcation. He remarks that there is no pain, the action take place *cito, tute et jucunde*.

Cocaine is said by Mr. W. Edmunds to be less liable to produce unpleasant symptoms if a 5 per cent. solution only be used for hypodermic injection (*Lancet*, p. 14).

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

On the Changes in the Blood during Pregnancy. By P. J. Meyer, Bern (*Centralblatt für Gynäkologie*, No. 47, 19th Nov., 1887).—The examination of the blood taken from ten healthy unimpregnated females, and from thirty-seven women in the last months of gestation, determines the diminution in the number of red blood globules from the early days to the end of gestation. In the puerperal condition the red globules and homoglobin increases, so that within a fortnight the number of red globules relatively exceeds that of pregnancy.

On the Absence of Microbes from Expired Air (*L'Union Médicale*, 10th Decembre, 1887).—MM. J. Strauss and W. Dubresnil have submitted observations upon the above subject to the Academy of Sciences, Paris. They observed that the air introduced into the pleural cavity as the result of fracture of the ribs, without external wound, produces infinitely less serious consequences than those which follow on pneumothorax from a penetrating wound of the lung. This, which had been to the authors a mystery, is explained by the germ theory, which shows that it is one of the functions of the bronchi to act as a filter to exhaled particles and prevent their entry to the air-cells. This explanation, the authors remark, is confirmed by the observation of Tyndal, who states that expired air is optically pure. This statement MM. Strauss and Dubresnil have endeavoured to verify by bacteriological methods of examination, and have substantiated Tyndal's conclusions, from which it is demonstrated that men or animals, confined in a small space, so far from polluting the atmosphere, on the contrary, *so far as microbes are concerned*, purify it. The effects of respiration on the inspired gases are not hereby alluded to.

The Employment of Pilocarpine in Pulmonary Disease. By Dr. Riess (*L'Union Médicale*, Nov. 24th, 1887, from *Berliner Klin Wochenschrift*).—Dr. Riess has found that in dropsy connected with pulmonary disease—the cough and dyspnoea—these symptoms have rapidly declined from subcutaneous injection of pilocarpine, secretion and expectoration having become abundant. On account of the expectorant action of pilocarpine Dr. Riess has used it in a series of cases of chronic bronchitis, in which other remedies had failed. An injection of 0.02 m. (= about $\frac{1}{2}$ gr. Eng.), or 0.01 in cases of extreme debility, given every alternate day. As a rule the effect lasts for forty-eight hours. In general twelve to fifteen injections, in from three to six weeks, effect complete amelioration in cases of asthma with emphysema. The pilocarpine has also been used with advantage by the author in chronic pneumonia; in whooping cough also, the dose being diminished according to the patient's age.

Treatment of Warts. By Bingley G. Pullin, M.R.C.S., Sidmouth (*Bristol Medico-Chirurgical Journal*, December, 1887).—Mr. Pullin has met with unexpected success in the treatment of warts on the hands of children by liquor arsenicalis, from one to three minims twice a day. In most cases the warts had disappeared in about ten days.

The Therapeutic Properties of Bromide of Iron (*L'Union Médicale*, 20th Novembre, 1887).—The bromide of iron, Dr. Hequet writes, possesses in the highest degree all the renovating properties of ferruginous medicines, and exercises, besides, a powerful sedative action upon the nervous system, diminishing, like other bromides, the after-sensibility. Hence it becomes a valuable remedy in various forms of anæmia, as it calms without depressing, and invigorates without excitement. From the year 1869 to 1887 Dr. Hequet has prescribed the bromide of iron in chlorosis, chloro-anæmia, leucorrhœa, amenorrhœa, and hysteria, with favourable results. In conjunction with Dr. Vacossin the author had observed beneficial results from the use of this medicine in diseases of the heart, in phthisis, diabetes, and epilepsy. Its beneficial influence over spermatorrhœa is also affirmed by the author.

On the Identity of the Œdema of Newborn Children with Phlegmasia Dolens. By Prof. Leon Dumas, of Montpellier (*L'Union Médicale*, 17th Nov., 1887).—Œdema of newborn children is distinct from the scleroma, or hardening of the cellular tissue, with which it has been confounded. It presents analogy from three points of view, with *Phlegmasia alba dolens*—viz., in its symptoms, etiology, and pathology. It consists in the presence of venous thrombosis, which had not previously been pointed out as belonging to the œdema of the newborn. Prof. Dumas has discovered this thrombosis in two veins of an infant in which this œdema was observed. This observation had been subsequently confirmed by other cases of newborn children of cachectic habit, in whom the respiration was feeble and the venous circulation

favourable to coagulation, especially in the umbilical vein. These pathological views indicate warmth as a main point in treatment, after the establishment of free respiration.

On the Parasitic Nature of Marsh Miasm. By Dr. Maurel (*L'Union Médicale*, 19th Nov., 1887).—From his researches into the above, Dr. Maurel has submitted the following conclusions to the Congress, at Toulouse:—It is always easy to distinguish healthy from marshy soil. The fauna and flora of marshy waters differ only in point of quantity from those of drinkable waters; the species which exist in the one may be found in the other. Marsh air differs from that of healthy districts in the presence therein of bodies which must be regarded as amœbæ in the course of development. These bodies are readily destroyed by desiccation, which is resisted the more that they are the less advanced in development; in the perfect state they resist incomplete desiccation. These researches, pursued through six years in France, in the Antilles, and in the extreme east, have shown that the same organisms that exist in the air of marshy regions have been found in the blood of persons suffering under marsh diseases. Dr. Maurel proposes to follow up his researches.

On the Etiological Bearing of the Bacilli of Tetanus (*Centralblatt für Chirurgie*, 10th December, 1887).—In the cases of two deaths from tetanus the communicability of the disease by bacilli was tested by their inoculation into mice, followed by tetanus and death (Beumer, *Berliner Klin. Wochenschrift*).

Observations on some of the New Hypnotics. By P. W. MacDonald, M.D. (*Bristol Medico-Chirurgical Journal*, December, 1887).—*Hyoeyamine*.—Dr. MacDonald is of opinion that the efficacy of this hypnotic should become generally known. "I prefer," he states, "and always use the extract. The most reliable preparation of the liquid extract is that known as Mercks's—expensive, but when made into a concentrated solution is easily dispensed, and will retain its strength for a long time. A convenient solution is one in 64. The dose of the extract is $\frac{1}{32}$ to $\frac{1}{2}$ gr., but you will seldom have to give more than $\frac{1}{4}$ gr." In recurrent cerebral excitement this is a useful remedy. When given continuously it is apt to accumulate and cause distressing dryness of the mouth and throat. It is most useful in robust subjects of maniacal excitement; its use is to be avoided in the weak or debilitated. Small repeated doses are better than one large dose.

Paraldehyde stands in same rank as chloral, but acts more speedily and gives a more natural sleep. Its action is gradual, and if it does not produce sleep it does not excite. It is a much more valuable hypnotic than many now in use. It may be employed in almost all instances of disturbed sleep, except when from mental excitement or severe pain. The dose is 3i. to 3ij., given in mucilage or syrup. In the selection of a hypnotic, the true cause of the patient's loss of sleep should be ascertained; we should note whether the case is one of simple restlessness or genuine wakefulness.

II.—NOTES FROM FRANCE.

By HASTINGS BURROUGHS, L.R.C.S.I., ETC.

At the Académie de Médecine M. Rochard read a paper on ligation of the internal iliac artery for pulsating tumour, situated in the gluteal region. The patient was a young man, who for several years had a tumour in the right buttock, in which distinct pulsation was observed. Compression of the external iliac artery was tried, but no change took place in the size or character of the tumour. The diagnosis was difficult, as several ideas presented themselves. Was it a sarcoma, an angioma, or an aneurism of the gluteal artery? The surgeon decided on seeing what would be the result of tying the internal iliac, for some kind of speculation became imperative, as the tumour was about to give way. Immediately that the artery was tied, all pulsation disappeared, and the tumour diminished greatly in volume, and the patient was much relieved. From day to day all went on well, but the man insisting on returning to his work too soon, the swelling returned, suppuration became abundant, and fifty-seven days after the operation death took place. The autopsy showed that the artery was entirely obliterated, and the fossa was filled with pus and clots. This operation was the thirteenth of its kind practised by surgeons for aneurism of the ischiatic or gluteal arteries, of which six were successful.

M. Richelot spoke on a case of persistence of the canal of Nück. A young girl, aged nineteen, came to the hospital with a small tumour in the right inguinal region, which during the last four years showed itself prominently at the summit of the right labia when in the perpendicular position; it disappeared when the horizontal position was assumed. An inguinal hernia was diagnosed, and the patient desiring an operation, as she said that her marriage had just been broken off by reason of it, her request was granted. M. Richelot at first reduced the tumour, and

having excised the integuments, a fibrous cord—resembling more a narrow sac than the round ligament—was brought to view, and immediately the operator entertained the idea of a congenital hernia, which subsequent dissection confirmed. The communication between the canal and the peritoneal cavity was much too narrow to admit the passage of the intestine or omentum, and no other tumour than that of hydrocele could be found in such a situation. The girl left the hospital ten days afterwards entirely healed. The author, in conclusion, insisted on the fact that many surgeons denied, that the canal of Nüeck could be pervious, and here was a case in point, the operator thinking that the case was one of congenital hernia, but he was not sorry to have been disappointed, as the result was very satisfactory. Referring again to the radical cure of congenital hernia, M. Richelot said that he considered the operation so benign that it should never be refused. He and his colleagues have operated 140 times successfully.

At the Société de Chirurgie, M. Terillon spoke on the use of sponges steeped in boiled water for antiseptic dressing. He considered that carbolic acid baths were powerless in the cleansing of instruments. He prefers putting them into boiling water on the spot, as water in ebullition could not contain any microbe hurtful to man. Such was the opinion of M. Pasteur. M. Terrier said that although boiling water might not contain any microbes, it might contain spores; and consequently, he would advise that the water should be boiled several times in order to destroy those germs. M. Terillon replied that if the water were employed immediately, the spores would not have time to germinate.

M. Terrier read a paper on electric sunstroke. At the great steel works of the Creusot, the workmen who were soldering steel by means of electricity were attacked with symptoms analogous to those seen in sunstroke. The face and neck became inflamed and painful, and the skin peeled off as in the first degree of burn; the eyes became congested, and photophobia was well marked, in spite of the well-smoked glasses which the men wore. M. Terrier said that he assisted once at a similar operation, to test the intensity of the light. He guarded his eyes with yellow and red glasses, and standing two yards away, he laid bare his arm for a few minutes. At first he felt nothing, but in about half an hour an itching was felt in the arm, followed by intense redness. He slept uneasily that night, and in four days desquamation took place, as from an ordinary sun-burn. What was the cause of all these symptoms? Colorific radiation could not be admitted, as it is well known that electricity emits but little heat. He thought the matter was very difficult to explain.

Professor Dieulafoy gave a lecture in the Faculté de Médecine on diagnosis of cancer of the stomach, which is well worth reproducing. He first mentioned what were considered as the classic symptoms of the disease—a dyspeptic condition of more or less duration, in which anorexia predominated; pain, sometimes of a very sharp description; vomiting of food; hæmatemesis of the coffee grounds type; and a tumour, easily diagnosed if situated at the pylorus or on the front of the organ, but difficult to find if situated at the cardiac end. The general symptoms are emaciation and decolouration of the skin. But it must be borne in mind that all these, or at least, some of the most important, may be met with in chronic gastritis, dilatation of the stomach, simple ulcer, or even in lesions which are situated far away from the organ. An error in the diagnosis in some of these cases would be followed by an error in the treatment which might be fatal to the patient. Trousseau relates two cases of chronic gastritis, which resembled almost in every point cancer of the stomach. One of them, a man of fifty, vomited all his food. He lost in three months forty pounds in weight, and ejected daily a lot of mucous liquid of a black colour, resembling soot, and such as is witnessed in certain forms of cancer of the stomach. The affection made rapid strides towards a fatal termination, and the autopsy showed no trace of cancer. It is thus seen how easily a wrong diagnosis may be formed. However, there is this in favour of chirurgic gastritis—the vomiting of glairy liquid, especially in the case of drunkards, occurs generally in the morning, and the patient does not wear that emaciated aspect as seen in cancer. Dilatation of the stomach might give rise to symptoms resembling malignant disease; but here the dyspeptic troubles greatly predominate. Flatulence, pain after taking food, and vomiting of certain kinds of ailments, are the chief features. Washing out of the stomach generally gives a relief not witnessed in cancer. Ulcer of the stomach has often induced an error in diagnosis, as well as cancer of the omentum and the pancreas. Are there any signs on which absolute reliance can be placed? Trousseau gives one—*phlegmasia alba dolens*. It was exactly that symptom which made him believe he had cancer of the stomach, and as is well known, he died of it a few months afterwards. However, phlegmasia is not an infallible sign, although of very great importance, as it has been often witnessed in other affections. Rounnelere thought that a decrease in the urea was a sure symptom, but a similar condition can be found in leucocythemia, hydatids of the liver, etc. According to Professor Dieulafoy, the only sign on which

absolute reliance can be placed is the presence of *chlorohydric acid in chyme*. A few drops of a concentrated solution of brilliant green—*vert brilliant* (?)—placed in a test tube containing distilled water, gives a blue tint. If the distilled water were replaced by fresh gastric juice, the colour produced will be slightly green; and if the muriatic acid be in excess, the colour will be green; but if, on the contrary, this acid be absent, the effect will be the same as in the case of distilled water. Now, in cancer of the stomach, chlorohydric acid is always greatly diminished, and often wanting altogether, according to Dr. Debove. Consequently, the continued absence of this acid in the gastric juice is a certain sign of cancer of the stomach.

III.—NOTES FROM RUSSIAN JOURNALS.

BY VALERIUS IDELSON, M.D., BERNE.

On the Influence of Acute Febrile Diseases on Syphilis.—In the *Voëno-Sanitarnoe Dëlo*, No. 47, 1887, p. 557, Dr. D. N. Jankovsky publishes a new illustration of this rather curious clinical fact, that an inter-current febrile disease may cure—at least, apparently—syphilis. A “splendidly-built and nourished” student, aged twenty-two, contracted syphilis early in October, 1886. On examining the patient in December, the writer found an indurated copper-red flat scar at the site of primary (preputial) ulcer; painless swelling and induration of the inguinal, cubital, and occipital lymphatic glands; rosy and copper-red circular or irregular spots, varying in size from a lentil to a pea, and studding the whole chest and abdomen, as well as the inner aspect of the thighs; and angina, with an intense copper-red discolouration of the faucial mucous membrane. On the fifth day after the appearance of the rash there supervened rigor, followed by high fever, general malaise, agonising pain in the right side of the chest, and, later on, by cough, with expectoration of a viscid rusty sputum and intense dyspnoea—in short, there developed croupous pneumonia. The treatment of the latter was limited to nursing. On the seventh day of the pulmonary inflammation the temperature suddenly fell from 40° to 36.7° C., the patient bathing in his perspiration for the next three days. During the febrile stage of pneumonia, no alterations in syphilitic symptoms could be observed on carefully examining the patient every day; but on the second day after the crisis, the rash began to markedly fade. Two days later only its traces, in the shape of a slight greyish pigmentation, could be detected. In a week the patient's skin became quite clean, the preputial scar softened, and the faucial mucous membrane assumed a normal appearance. When seen in August, 1887, the patient did not present any traces of syphilis, and was in excellent health, which he had been enjoying ever since his recovery from pneumonia. Not a particle of mercury or iodine has been used in the case.

[That syphilitic symptoms may undergo an alteration under the influence of supervening acute fevers—such as croupous pneumonia, erysipelas, typhoid and typhus fevers—is admitted without any dispute by all dermatologists and syphilographers. It is otherwise, however, as regards the question as to whether acute fevers can cure syphilis, or not. The German school in general (F. A. Simon, Zeissl, Baeumler, J. Neumann, Hebra, sen., Kaposi, Gruenfeld, etc.) seems to admit only the possibility of a temporary alleviation or disappearance of syphilitic phenomena. Meanwhile, the international literature contains a series of observations which, like Jankovsky's case, apparently prove that syphilis can be actually cured by an inter-current febrile disease. Similar cases are mentioned by Giraudeau de St. Gervais (1825 and 1838). In 1860 Professor Eltzinsky, of Moscow, having carried out a series of clinical experiments on the treatment of syphilis by vaccination, arrived at the conclusion that the development of a reactive fever in his vaccinated syphilitic patients represented an essential condition for obtaining a successful result (that is, a complete cure) from his method. Having repeated Eltzinsky's experiments, Dr. Eiland laid down (*Voëno-Meditzinsky Jïrnal*, July, 1860) the proposition that “when syphilis was cured by vaccination, recovery ensued solely under the influence of a febrile state caused by the introduction of vaccine lymph into the syphilitic patient's system.”]

According to Dr. J. Petrovsky (*Vratch*, No. 22, 1881, p. 360), cases of syphilis cured by acute fevers were published in Russian journals, also, by Drs. Lavrentieff, Behrenson, and Spiro. Dr. Petrovsky himself came across three cases of the kind. In one of his patients, a strong man, aged thirty, admitted with syphilitic symptoms of about six months' duration, there were present diffuse induration of the whole foreskin, a shallow indurated ulcer on the lower aspect of the prepuce, acute phimosus, balanitis, flat warts on the glans, numerous moist papulæ over the scrotum, extensive mucous patches in the fauces, papulous syphilides with a slight desquamation over the scalp, and cutaneous tubercles, as big as a pea, over the face. A six weeks' course of mercury failed to effect any improvement, beyond some trifling softening of the preputial induration, and a slight diminishing and

drying of the scrotal syphilides. About the end of two months since his admission, the man somehow managed to contract an extremely severe confluent small-pox, accompanied by a high fever with cerebral symptoms. On his recovery from the attack, not a trace of syphilis, or any sign of syphilis, could be detected. Another patient, a strong soldier, aged twenty-seven, was first admitted with cutaneous and mucous syphilides, faucial ulcers, and induration and swelling of numerous cervical glands. After a course of mercury, he was discharged seemingly cured, the only trace left being a hard nodule, of the size of a largish pea, situated beneath the right angle of his lower jaw. A year elapsed, during which period the man occasionally suffered from night-pains in his legs. By the end of the said time he again came under Petrovsky's care, and that on account of a severe attack of typhoid fever. On his admission, the author found that the former hard and deeply-seated sub-maxillary nodule had transformed into a superficial, adherent, soft, flabby, roundish tumour, of the size of a big walnut—that is, into a gumma of subcutaneous cellular tissue. About the period of his re-convalescence from typhoid, the tumour spontaneously gave way to discharge a brown, viscid, semi-fluid matter. The cavity soon healed, the man leaving the hospital only with a slight brownish discolouration, and a small soft scar at the spot. No remedies were used, except anti-pyretics. The author's third patient, a well-made and nourished soldier, aged twenty-three, was admitted on account of facial erysipelas with a high fever. On examination, there were found also superficial ulcers on the penis, tumefaction of the inguinal and cervical glands, sore throat, and flat condylomata on the soft palate and oral mucous membrane. In a fortnight, not only erysipelas, but also all syphilitic phenomena disappeared tracelessly. No anti-syphilitic remedies were used in the case. No relapse occurred in any of the men, everyone of whom remained under the writer's observation for several subsequent years.

Dr. F. E. Cudzinowicz, of Kütaïs, also saw (*Proceedings of the Caucasian Medical Society*, No. 6, 1884, p. 134) a case of a curative action of erysipelas on syphilis. His patient, an emaciated and exhausted Imeretin horseman, aged twenty-five, was admitted on the fifth day of bullous erysipelas of his left thigh. There were found also enlargement and induration of inguinal and cervical glands; a cinnamon-brown, marble-like discolouration and star-like scars over the skin of his loins, buttocks, and chest; intense periostitis of both of the tibia, with severe spontaneous pain and extreme tenderness; and a fairly deep enormous ulcer, occupying the front and sides of the right leg (more than one-third of its whole surface), with a dirty-greyish bottom, sharply-cut edges, and a thin purulent discharge. According to the patient's statements, about two and a half years previously he had contracted syphilis, from which he had been subsequently treated for more than a year. The crural ulcer had made its appearance about four months before his admission, to steadily increase ever since. Erysipelas of the thigh remained localised, to completely disappear on its eleventh day, the temperature never rising above 38.5° C. By the end of twelve days since his admission, the crural ulcer was found to be not larger than a shilling-piece, of a rosy colour, and filled up with healthy granulations; a "disgusting" mottled appearance of the integuments strikingly decreased, "as if from resorption of the pigment," and tibial pain ceased. A month later only a scar was present at the site of the crural ulcer (which, as the author thinks, had had an ecthymatous origin); lymphatic glands became softer and smaller; while not a trace of tibial periostitis could be detected, the inflammatory exudations having undergone a complete absorption. The man left the hospital in a considerably improved general state. Dr. Cudzinowicz adds that he happened to meet frequently cases of syphilis combined with malarial fevers. The influence of the latter on the former is said to be far from presenting any uniformity. As far as a freshly-contracted intermittent fever with a regular and rapid course is concerned, it may give rise to a considerable and durable improvement, or even to a complete disappearance, of various localized or circumscribed manifestations of late syphilis (such as gummatous ulcers, myositis, periostitis, etc.). Early syphilides may also rapidly dwindle away, but only temporarily, to reappear after the patient's recovery from the fever. As to malarial cachexy, and irregular types of intermittent with a torpid course, they invariably produce an extremely unfavourable influence on symptoms and run of syphilis of any form.

In the *Meditzinsky Vestnik*, No. 7, 1884, Dr. N. Schmitz describes the case of a syphilitic man with intractable callous tubercular ulcers, who, "for the sake of experiment," was placed side by side with an erysipelatous fellow-patient. On the next day—so the author says—erysipelas appeared in the neighbourhood of an ulcer to wander on, subsequently, over the whole body and limbs, from one callous ulcer to another, for seven days. From the very beginning, unmistakable signs of a "revival" of a formerly "dead" granulation tissue were said to be noted. In another week all the ulcers were full of benign granula-

tions, to swiftly heal altogether. According to Dr. Schmitz's views, in one group of syphilitic cases the curative effects of erysipelas are analogous to those of derivative means, such as tincture of iodine, or blisters. In another group the effects in question consist in causation of a fatty degeneration of morbid products, with a subsequent resorption of thus degenerated histological elements, while in a third category of cases they are essentially based on a gangrenous disintegration of morbid new growths.

Dr. A. A. Fedotoff, of Cronstadt (*The London Medical Record*, December 15th, 1883, p. 512), recorded a case of the disappearance of syphilis from croupous pneumonia. Dr. V. Volsky, of Bendery (*ibid.*, July, 1887, p. 308), described an instance of a fleeting suppression of all syphilitic manifestations under the influence of erysipelas. A rapid cure of syphilitic tubercles of the face by erysipelas was once observed also by Dr. Minelli (*ibid.*, November, 1884, p. 463). Professor Pick (*ibid.*, August, 1883, p. 338) published two interesting cases of a rapid resorption of gummata, caused by an inter-current attack of the same acute fever. Similar observations were reported further by Drs. Lancereaux, Baeumler, Bidenkap, etc.—*Reporter*.]

Congenital both-sided Anophthalmos.—Dr. Strzemiński (pronounced "Stsheminski," a Polish name) records (*Vratch*, No. 49, 1887, p. 950) a rare case of a congenital complete absence of both of the eyeballs, found by him in an otherwise normally-developed child, aged two weeks (its sex not stated). The eyelids were closed and, being devoid of any support behind, could be very easily depressed into the orbits. The palpebral slit was somewhat narrower comparatively with the normal conditions. On separating the eyelids, there was seen a small cavity lined with a normally-looking mucous membrane joining, without any demarcation, with the palpebral one. The lachrymal caruncles were absent, while the lachrymal glands seemed to be present, since there was noticed the secretion of a tear-like fluid. [A similar case was communicated some time ago by Dr. Kvashonkin, *vide* the *London Medical Record*, 1883, p. 245].

Violent Hæmorrhage from Hymen on First Coition.—At a recent meeting of the Kiev Obstetrical and Gynecological Society, Dr. Boriakovsky read an interesting paper (*Vratch*, No. 47, 1887, p. 917) on the case of a medical man's wife, aged seventeen, in whom, after the first coitus, an extremely violent hæmorrhage from her ruptured hymen had followed, the lady repeatedly falling into deep swoons. The hymen was found to be rather thick, its free edge being broken at several spots. At the bottom of one fairly-deep rupture there was detected a profusely-bleeding small vein. The hæmorrhage ceased after Dr. Boriakovsky had sutured the vessel, as well as another bleeding small fissure in the neighbourhood of the former laceration. Three days later, the hymenal hæmorrhage reappeared, but was less severe this time, and could be easily arrested by the patient's husband, by applying a solution of perchloride of iron. The author thinks that in his case there existed an anomalous excessive vascularisation of the membrane.

IV.—EXTRACTS FROM SPANISH AND OTHER MEDICAL JOURNALS.

TRANSLATED BY DR. G. CADOGAN MASTERMAN.

Enfermedad de los Buzos (Diver's Paralysis). By Dr. D. Rosendi Pi, Barcelona (continued from page 38).—Compressed air, which is now occasionally used as a therapeutic agent, becomes pathogenic when it is inhaled too long, and at too high pressures; but it is most interesting to observe how slight these effects are when the tension, even when high, is tolerably constant. A large number of the divers carry on their hazardous calling without any evil effects whatever when care is taken to increase, and especially to decrease, the pressure gradually. Others complain greatly of the oppressed breathing and the tendency to syncope, much, of course, depending upon individual peculiarities, and particularly on the possession of coolness and presence of mind in the face of danger. One of them was telling the author that, having become entangled in a bed of seaweed, he was struggling for more than two hours, at a considerable depth, before he got free, and the only trouble was the difficult breathing, and the somewhat profuse spitting of blood when he reached the surface. The greater mischief is done when the pressure is taken off too suddenly, as when from some accident, or the fear of it, the man is hauled rapidly to the surface, and the dress removed before the circulation has had time to re-adapt itself to the abruptly changed conditions. This has been explained by reference to the law regulating the behaviour of gases, dissolved in liquids under pressure, when that pressure is lessened or removed. It is then found that so much of the gas is given off as represents the difference of the volumes which the given liquid could hold in solution at the former and the latter pressure, supposing the temperature to be constant; but, if the temperature rise coincidently with the reduction in tension, then a further quantity of gas escapes, as Dalton determined in the case of

carbonic acid dissolved in water. Now, in the case of these coral divers, we have respiration—that is, gaseous endosmosis—carried on under greatly increased pressure, and with the surface of the body and its subjacent blood greatly lowered in temperature by the cold sea water; and we should expect that when this pressure was suddenly removed, and in the much warmer atmosphere, that a kind of effervescence would take place within the blood-vessels, with some approach to the terrible consequences which result when air is admitted into the veins. And the theory first advanced by Hoppe in 1857, and later by Rameaux and Bert, is that this evolution of gases within the capillaries, with consequent arrest of the circulation, explains the pleuro-cardiac phenomena and the cerebro-spinal mischief we see the divers so often suffer from. To this conclusion, however, there are several objections. In the first place, there is no real similarity between a gas dissolved in water, and air and carbonic acid diffused in blood. The latter gas is not simply held in solution in the serum, but chiefly in temporary combination with the alkaline carbonates and phosphates, the water of the blood taking up at the normal temperature very little, and in the former condition its tension is *nil*. Of the oxygen, again, very little is dissolved, the greater part combining with the hæmoglobin of the red cells, and is no longer affected by pressure. As regards the nitrogen, Setchenow has shown by experiments on dogs that only a very small amount is absorbed—too small, in fact, to influence the results.

Now, the researches of M. Bert himself have shown that the law of Dalton does not hold good in the case of the absorption of oxygen by the blood under pressure. It is true that more is then taken up, but the ratio lessens as the pressure increases, even up to ten atmospheres. And the process of oxidation, which leads through various intermediate stages to the formation of carbonic acid in the blood, is lessened as the pressure increases, because the initial process is checked by the presence in excess of the very carbonic acid it tends to form. It is only the nitrogen, which forming no alliance in the blood, is free to follow the law of gaseous absorption, and is, according to M. Bert, the agent which leads to this hypothetical capillary obstruction. But the solubility of this gas in water is extremely small,¹ and the experiments of Bert have been shown to be fallacious by the researches of MM. Mathieu and Urbain. The strongest objection to the theory is, however, that as all the divers are subjected, more or less, to the same conditions, they should all suffer from a cause which is common to them; and especially, that those working at great depths should experience them, and that the lungs, which have to bear the change first, should suffer primarily and most severely, which we have seen is not the case. And, again, the notable influence of the moral condition of the diver is untouched by it. In shallow water, and under slight pressure, the worst accidents have happened to men suffering from timidity or some sudden terror. It cannot be believed that a psychical cause could lead to increased gaseous tension, or the mechanical liberation of air within the capillaries.² But, on the other hand, terror can, by leading to the contraction of the superficial vessels, cause internal congestion, and this leads to the theory propounded by M. Foley in 1863. This observer records the striking pallor of the skin and mucous surfaces of the men working in the caissons of the bridge of Argenteuil, and the diminution and even extinction of the pulse. And although he only noticed slight surface extravasations and muscular tremors, from the blood suddenly filling the previously empty vessels on the return to the open air (the pressure was never greater than from one to three atmospheres), he showed how the same conditions within wider limits could lead to the gravest mischief. The author would term this condition hæmatomyelia; for it is evident from the results that there is not merely compression of the cord through the cerebro-spinal fluid, but also within its substance from engorgement of the perforating branches of the spinal arteries, and this satisfactorily explains the train of formidable symptoms so often culminating in paraplegia, and occasionally in death.

And the conditions under which the divers work all tend to promote, the author contends, first anæmia of the cord, and, on their return to the surface, a compensatory hyperæmia, which if gradual in its approach is harmless, but if sudden disastrous. They have always to work under great pressure, the (red) coral-bearing rocks never being found at a less depth than twenty fathoms (nearly three atmospheres), and generally lying much deeper; this not only affects respiration, but nearly the whole of the surface of the body is compressed as if by tight bandaging; below the waist and the wrists there is no elastic air cushion to lessen it; so the heavy and frequently very cold sea water presses with leaden weight on the abdomen and legs, and at the greatest depths the action

of the pump is often so imperfect, that it is as much as it can do to keep the helmet full without inflating at all the dress covering the back and chest. From the symptoms described in the ten illustrative cases, it is clear that the worst mischief is seated in the medulla spinalis; that in the brain would seem to be simple compression, possibly that "serous apoplexy" which so often figures in our supposititious death certificates. But it is by no means clear that this is due to sudden reduction in pressure.

It should be noticed that Dr. Pi never accompanied the divers in their work, and that he really personally treated but one case—the last—and he mentions the very inexact and confused statements he heard from the men often long after the incidents occurred. From the position of the spinal cord, its serous, bony and muscular coverings, and the sources of its blood supply it, surely forms part of the internal organs of the body, and when the blood from the skin and superficial muscles is driven inwards by the combined cold and pressure, it is then one would expect the results due to engorgement to shew themselves, not when the blood returns in normal quantity to the surface. And, it is evident from the graphic descriptions of the corpse-like faces and icily-cold bodies of those who suffered most severely, that it was when this healthy reaction did not occur that mischief ensued, which gradually increased in intensity, most probably from engorgement having been followed by extravasation of blood within the cord or its *pia mater*.

As regards treatment, the author speaks highly of that used by the divers themselves: the vigorous rubbing of four pairs of horny palms, somewhat mitigated by powdered stæatite, until the patient return to consciousness, or (he naively adds) to paralysis or death. But from the examples given the results are not encouraging, and No. 8, who refused to submit to this regimen, and simply lay down on the deck warmly covered up, seems to have fared as well or better than those who did. The more regular treatment advocated by hard purging, cupping, leaching the anus and counter irritation, would meet with little favour amongst English practitioners. But it would be very interesting to learn from our naval surgeons, who must have occasionally watched the service divers at work, if they have noticed any similar results, and especially, if these men have contributed any cases of diver's paralysis.

Two Cases of Cure of Deaf-Mutism from Otopiesis. By Dr. D. P. Verdós (*Rev. Cien. Med.*, Barcelona, December, 1887).—Within recent times treatment of the diseases of the auditory apparatus has advanced so much, that the greater number have lost their old reputation of hopeless incurability, but the many deaf-mutes seen amongst us are still a reproach to this branch of medical specialism, and the more so as it is being apparently conclusively proved that congenital cases of the defect are really so rare that it can scarcely be said that they exist: the error arising from the fact that the initial mischief is overlooked until it is too late to remedy it. To show what can be done by appropriate treatment, even in the least promising cases, the two appended will show:—

Enrique, a child of about five years of age, robust and healthy, and with no other defect than deafness and consequent inability to speak. He throve when an infant, but the parents soon noticed with dismay that he could hear none but the loudest sounds, and could not utter a syllable. A doctor was consulted who advised waiting, with the assurance that all would be well in time; and this was done until the still voiceless child had reached the above age, when Dr. Verdós was consulted as a specialist. On examination he was at first inclined to put down the case as incurable, but, by watching the boy's face as he moved a vibrating tuning fork in contact with his head, he noticed such a change in expression that it was evident the sounds were faintly heard, although the child could not utter a syllable in evidence of it. However, as it was clear that the auditory nerve was not altogether destroyed, treatment was undertaken with the understanding that it must necessarily be tedious, and possibly abortive. The tympani were found bulging excessively from purulent fluid in the vestibule, and the Eustachian tubes were completely blocked; the mischief having apparently commenced there with neglected catarrh and then extended to the middle ear. By gentle and persevering catheterism, injection of air through the gradually opened tubes, and douches of alternately compressed and rarified air in the meatus externus, the potency of the former was restored, the vestibules emptied and the tympani restored to their normal form, and with such success that at the end of two months the child could hear sounds of all kinds including the ticking of a watch, and, which was of far more importance, was beginning to understand the meaning of simple words. A little later he began to form syllables for himself, and at length to speak as well as children of his age ordinarily do.

The second case was that of a child named *Pepe* (Joey), about four years old, of lymphatic temperament, feeble constitution, and with an air of the utmost stupidity; he was absolutely deaf, and had never uttered a single word. With him the auditory faculty seemed to be

¹ Brande (*Man. Chem.*, p. 326) says nitrogen is not absorbed by water unless the whole of the air in it has been expelled by long boiling, and then only to the extent of 1.5 per cent. (*Trans.*)

² Although this seems a very reasonable explanation of the extraordinary meteorism so often seen in hysterical cases (*Trans.*)

utterly abolished, he showed no signs whatever when the tuning-fork vibrated in contact with different parts of his head. The condition of the tympani and tubes was identical with that of the preceding case, and, although any chance of success seemed exceedingly remote, the same treatment was pursued, and, most unexpectedly, with equal success. From the feeble mental condition as well as the more tender age of *Pepe*, he did not get on quite so fast as the other, nevertheless, both in hearing as in speaking he did all that could be expected of him.

Chromatic Audition (*De L'Audition Colorée*). By J. Baratoux (*Le Progrès Médical*, Paris, December 24th, 1887).—Some years ago a kind of chromatic piano was exhibited in London which emitted no sound, but showed octaves and chords of spectra and harmonies of complementary colours. The effect was said to be quite too lovely by the inventor, but an unappreciative public laughed at him, and the machine was soon forgotten. It seems, however, that in France and Germany many sensitive people exist, who habitually, by a process of unconscious cerebration, connect certain sounds and colours, like the blind man who, having gained the power of seeing, always associated "red with the sound of a trumpet;" but then, it may be observed, that as many trumpeters are clothed in scarlet the combination might have been simply visual after all. The proportion is said to be as high as 12.5 per cent. of those tested in Germany, and in some it is so pronounced that they see a halo of the conjoined colours playing around the strings of a violin or guitar when in vibration. Now it has been stated that if the middle C wire of the piano could be bi-sectioned thirty-two times, and then be made to vibrate it would emit not sound but a yellowish-green light, but these more impressionable (imaginative?) subjects perceive it when the wire is still of its ordinary length. Others, again, link certain tastes and odours with particular sounds, even as we more matter-of-fact Englishmen experience certain agreeable gustatory sensations when the second dinner bell is sounding. As the idea of colour in these cases, as well as that of taste, is purely subjective, the author of the two long articles can bring only hypothetical reasoning to bear upon it, and fairly quotes the opinions of others who look upon it as a very pleasing and harmless hallucination; and, as wit has been said to consist in finding similarities in perfectly dissimilar objects, may not it be looked upon altogether as an æsthetic *jeu d'esprit*? It explains, however, a very puzzling verse in a sonnet of Verlaine's which runs:—"A noir E blanc I rouge U vert O bleu, voyelles. . . ." And Théophile Gautier after taking haschisch says, "I heard the sounds of the colours—green, red, blue, yellow—tones in waves of harmony; and a falling glass, a creak of my arm-chair vibrated and rolled in peals of lurid thunder!"

V.—INTERNATIONAL MEDICAL CONGRESS.

SURGICAL NOTES.¹

(Continued from page 43, January, 1888).

WE gave an abstract of Dr. Parkes' paper in the November number, 1887, p. 522, and referred to the valuable paper by Dr. Nicholas Senn, of Milwaukee, Wis., entitled *An Experimental Contribution to Intestinal Surgery, with Special Reference to the Treatment of Intestinal Obstruction*.—*Artificial Intestinal Obstruction*.—*Stenosis*. (a) *Partial Enterectomy and Longitudinal Suturing of Wound*.—Traumatic stenosis from this cause becomes a source of danger from obstruction or perforation in those cases where the lumen of the bowel is reduced more than one-half in size. Longitudinal suturing of wound on the mesenteric side of the intestine should never be practised, as such a procedure is invariably followed by gangrene and perforation by intercepting the vaso-motor supply to the portion of bowel which corresponds with the mesenteric defect.

(b) *Circular Constriction of Intestine*.—The immediate cause of gangrene in circular constriction of a part of intestine is due to obstruction of the venous circulation, and takes place first at a point most remote from the cause of the obstruction.

2. *Flexion*.—(a) *Flexion Produced by Partial Enterectomy and Transverse Suturing of Wound*.—On the free surface of the bowel a defect an inch in width can be closed by transverse suturing without causing obstruction by flexion. In such cases the stenosis is subsequently corrected by a compensating bulging, or dilation of the mesenteric side of the bowel. Closing a wound of such dimensions on the mesenteric side of the bowel by transverse suturing may give rise to intestinal obstruction by flexion, and to gangrene and perforation by impairing the arterial supply to, and venous supply from, the portion of bowel corresponding with the enteric defect.

(b) *Flexion caused by Inflammatory and other External causes* gives rise to intestinal obstruction only in case the functional capacity of the flexed portion of the bowel has been diminished or suspended by the

causes which have produced the flexion, or by subsequent causes independently of the flexion.

3. *Volvulus*.—As in flexion a volvulus gives rise to symptoms of obstruction when the causes which have given rise to a rotation upon its axis of a loop of bowel have at the same time produced an impairment or suspension of peristalsis in the portion of bowel which constitutes the volvulus, or when a diminution or suspension of peristalsis follows in consequence of the rotation.

4. *Invagination*.—Accumulation of intestinal contents above the seat of invagination is one of the most important factors which prevents spontaneous disinvagination and which determines gangrene of the intussusciens. Spontaneous reduction is not more frequent in ascending than descending invagination. The immediate cause of gangrene of the intussusciens is obstruction to the return of venous blood by constriction at the neck of the intussusciens. Ileocaecal invagination, when recent, can frequently be reduced by distension of the colon and rectum with water, but this method of reduction must be practised with great care and gentleness, as over-distension of the colon and rectum is productive of multiple longitudinal lacerations of the peritoneal coat, an accident which is followed by the gravest consequences. The competency of the ileo-caecal valve can only be overcome by over-distension of the caecum, and is effected by a mechanical separation of the margins of the valve; consequently it is imprudent to attempt treatment of intestinal obstruction beyond the ileo-caecal valve by injections per rectum.

Enterectomy.—Resection of more than six feet of the small intestine in dogs is uniformly fatal. The cause of death in such cases is always attributable to the immediate effects of the trauma. Resection of more than six feet of the small intestine in dogs is incompatible with normal digestion, absorption, and nutrition, and often results in death from marasmus. In cases of extensive intestinal resection the remaining portion of the intestinal tract undergoes compensatory hypertrophy, which, microscopically, is shown by thickening of the intestinal coats and increased vascularisation.

Physiological Exclusion.—Physiological exclusion of an extensive portion of the intestinal tract does not impair digestion, absorption, and nutrition as seriously as the removal of a similar portion of resection. Faecal accumulation does not take place in the excluded portion of the intestinal canal. The excluded portion of the bowel undergoes progressive atrophy.

Circular Enterorrhaphy.—A modification of Jobert's invagination-suture by lining the intussusceptum with a thin, flexible, rubber ring, and the substitution of catgut for silk sutures is preferable to Czerny-Lembert sutures. The line of suturing on neck of intussusciens should be covered by flap or graft of omentum in all cases of circular resection, as this procedure furnishes an additional protection against perforation. In circular enterorrhaphy, continuity of the peritoneal surface should be secured when the mesentery is detached by uniting the peritoneum with a fine catgut suture before the bowel is united, as this modification of the ordinary method furnishes better security against perforation on the mesenteric side.

Intestinal Anastomosis.—The formation of a fistulous communication between the bowel above and below the seat of obstruction should take the place of resection and circular enterorrhaphy in all cases where it is impossible or impracticable to remove the cause of obstruction, or where the pathological conditions which have given rise to the obstruction do not constitute an intrinsic source of danger. Gastro-enterostomy and jejunostomy should always be made by approximation with partially or completely decalcified perforated bone-plates. In making an intestinal anastomosis for obstructions in the caecum or colon, the communication above and below the seat of obstruction can be established by apposition with decalcified perforated bone-plates, or by lateral implantation of the ileum into the colon or rectum. An ileo-colostomy, or ileo-rectostomy, by approximation with decalcified perforated bone-plates or lateral implantation, should be done in all cases of irreducible ileo-caecal invaginations where the local signs do not indicate the existence, or occurrence, of gangrene and perforation. In all cases of threatened gangrene and perforation the invaginated portion should be excised, both ends of the bowel closed, and the continuity of the intestinal canal restored by making an ileo-colostomy by approximation with perforated decalcified bone-plates or by lateral implantation. The restoration of the continuity of the intestinal canal by perforated approximation-plates, or lateral implantation, should be resorted to in all cases where circular enterorrhaphy is impossible on account of the difference in the size of the lumina of the two ends of the bowel. In cases of multiple gunshot wounds of the intestines involving the lateral, or convex, side of the bowel, the formation of intestinal anastomosis by perforated decalcified bone-plates should be preferred to suturing, as this procedure is equally, if not more safe, and requires less time.

¹ Taken from the *Medical Record and Register*, Philadelphia.

Adhesion Experiments.—Definitive healing of an intestinal wound is only completed after the formation of a network of new vessels in the product of tissue-proliferation from the approximated serous surfaces. Under favourable circumstances quite firm adhesions are formed between the peritoneal surfaces within six to twelve hours which effectually resist the pressure from within outward. Scarification of the peritoneum at the seat of approximation hastens the formation of adhesions and the definitive healing of intestinal wounds. Omental grafts, from one to two inches in width, and sufficiently long to completely encircle the bowel, retain their vitality, become firmly adherent in from twelve to eighteen hours, and are freely supplied with blood-vessels in from twenty-four to forty-eight hours. Omental transplantation, or omental grafting, should be done in every circular resection, or suturing of large intestinal wounds, as this procedure favours the healing of the visceral wound and furnishes additional protection against perforation. The speaker presented some valuable specimens in which the operation had been performed on dogs; these specimens fully illustrated the value of the method advocated, and its entire feasibility, the union in some of these specimens being most remarkable. He called attention to its use in stenosis of the pyloric orifice. The duodenum or the first convenient coil of intestine being connected with the stomach by the method advocated, adhesions would form in from fourteen to twenty-four hours. The adhesions in the specimens shown were wonderfully firm and strong.

Dr. W. T. Oppenheimer, of Richond, Va., exhibited in section of anatomy several photographs of **An Apparatus for the Treatment of Fractures of the Surgical and Anatomical Neck of the Humerus**. He spoke of the great difficulty in keeping the fractured extremities of the bone in apposition, and thought that his apparatus covered the three necessities of extension, counter-extension, and fixation. The apparatus consisted of strong iron bands, which were fastened around the thorax by means of plaster of Paris, and which extended to the fractured arm, holding it firmly at the shoulder, upper arm, and forearm. He had used it in several severe cases of fracture of the neck of the humerus, and suggested using it in fracture of the clavicle and in excision of the elbow-joint.

The President, Dr. Pancoast asked when passive motion was commenced.

Dr. Thomas, of Pittsburg, Pa., thought it did not matter what apparatus was used, so long as the arm was held out from the body. He admitted, however, that he had never treated a case in that way, but thought it formed the principle of Dr. Oppenheimer's apparatus.

Dr. Oppenheimer replied that in about five weeks passive motion was commenced. He said when the plaster jacket was put on well, and the bands were strong, that no movement of the body could cause crepitation.

The President asked if a corset of leather or of other material could not be used instead of the plaster of Paris, which, in his opinion, seemed a little clumsy for such treatment. He also thought that in using crepitation there was danger of tearing the periosteum, and thus cutting off the blood-supply of the fractured ends.

Dr. John Homans, of Boston, read a paper entitled **Three Hundred and Eighty-Four Laparotomies for Various Diseases, a résumé of the writer's experience**. In these cases he was in the habit of using drainage-tubes, cleaning them once in about four hours; but he did not consider that they drained the abdominal cavity, although Keith, of Edinburgh, has in his possession about two gallons of fluid secured in this manner from one patient. In his own practice, he had had one case of tetanus after laparotomy, the patient dying at the end of six days; one case of stone in the bladder, from hair, falling in, forming a nucleus. The greatest number of consecutive recoveries he had had was thirty-eight. He considered that suppurative cysts of the ovary were very rare, only one having come under his notice, and he believed that they did not exist unless exposed to the air or a mucous surface. The removal of sessile tumours was quite a knack, which was only acquired after long experience. The preference of procedure by the writer was the extra-peritoneal, using the wire écraseur, and if the bladder was injured during the operation a soft catheter was retained in the urethra. In five cases of bleeding fibroids, one he had cured, the second relieved in part, and the third received no benefit. Another case, in which the uterus was removed, the patient died. In one case of abscess of the ovary, the patient recovered. The writer called attention to that condition in which feces exude from the umbilicus through a tube called the "omphalo-mesenteric remains," one case coming under his care. The patient afterwards died from marasmus. One case of tubercular peritonitis he had cured. He had had five cases of artificial anus, with three cures; one case of cystic tumour in which, during the operation and opening of the sac the woman gave a violent cough, and the cyst was forced clean out by the effort. In one case of laparotomy, performed January 27, 1886, the patient was con-

fined in December of the same year. A case of fibroid tumour of the uterus was gradually expelled through the wound in the abdominal wall. The speaker saw no reason why contractions should not occur in this manner as with any other foreign body in the uterus; the removal of uterine appendages in his own practice for nervous diseases had not given good results, only one case being cured; a woman who was very violent during her menstrual period, and who had commenced sexual intercourse at seven years of age, was relieved of her mania, but her mind was weak. He had had two cases of myxo-lipoma, one in a man and the other in a woman; the man died eight hours after the operation. The speaker had performed laparotomy upon him once before, but refused to remove the tumour; the second time the man begged to be relieved of it, and the attempt was made, fifty-two pounds being removed, and other portions were left. He had performed laparotomy once for perityphlitic abscess, and the patient recovered.

Dr. Addinell Hewson, of Philadelphia, presented a paper (which was read by the Secretary) purporting to claim that the main point in laparotomy was the closing of the abdominal wound without sutures. This was done by means of binders' paste and a certain prepared gauze, called **Donna Maria's Gauze**, and which was first made some forty years ago; this gauze, however, cost \$5 per yard. The writer was not partial to wet dressings, and the present paper was reserved to dry dressings.

Dr. I. M. Matthews, of Louisville, Ky., read a paper entitled **When is Colotomy Justifiable?**—The writer had had twenty years' experience in rectal surgery, and he did not consider colotomy justifiable in cancerous disease of the rectum when located three inches from the anus; again, not in stricture beyond the reach of the finger, nor in aneurism, nor in cases of specific origin. In most of these operations life was not prolonged; he had seen as many live without it as with it. The speaker considered the pain in cancer to be inherent. In the division of stricture, he did not consider there was any danger, as the hemorrhage could be controlled. In small ulcers of the gut, he did not believe in operating, antiseptic and internal treatment being preferable, using proper nourishment in such cases. In congenital occlusion of the rectum he did not think it should be recommended, but that the perineal operation should be done. When the sigmoid flexure is blocked the speaker thought it justifiable. The question then arises, what is to be done in the majority of cases for stricture? Linear rectotomy, not colotomy.

The paper was discussed by Professor Dawson, of Cincinnati, O., who quoted a case of cancer of the rectum within reach of the finger; patient suffering fearfully, and upon whom he intended to operate. He agreed generally with Dr. Matthews. He had really never performed colotomy which gave him satisfaction. In syphilitic cases of stricture he had found they could be treated constitutionally.

Dr. Quimby, of Jersey City, asked how nearly the gut was occluded.

Dr. Dawson replied to about the size of the little finger, the edges hard as wood.

Dr. Quimby agreed with Dr. Matthews on this point, and thought there would not be much gained.

Dr. Samuel Benton, of London, England, remarked that if he could get beyond the cancer he performed the operation, but if the growth was high up he performed colotomy. It had not been his experience that colotomy should not be performed in cancer of the rectum; his last case lived sixteen months after; he considered pain was relieved by colotomy. Cases of benign stricture he treated with electrolysis.

Dr. Hamilton, of Columbus, O., gave most rigid cautions against the use of carbolic acid in the rectum, the use of which he could not condemn too strongly.

The discussion of abdominal surgery was first taken up. Dr. W. N. Hingstone, of Montreal, thought that when any doubt existed as to the course of the bullet, operative procedures were necessary. The speaker considered the paper by Dr. Senn the most able he had ever heard. Regarding Dr. Homan's paper, he had mentioned that ventral hernia occurred in ten per cent. of his cases; this the speaker considered rather large. Dr. Homan had stated that he had operated for nervous affections in five cases; one was relieved, the other four were not; other professional men had given the opposite result. The speaker remarked that he believed Dr. Homan, but did not believe the others.

Dr. J. B. Murphy, of Chicago, remarked that in regard to the incision being made in the median line, he was in one case compelled to deviate from this rule in order to reach the gut. If the operation is not dangerous to life, he considered it compulsory, and if the bowel is not injured it does no harm.

Dr. W. T. Peck, of Davenport, Ia., remarked that as regards foreign substances in the peritoneal cavity, he had put forty-seven sutures in an ovarian cyst.

Dr. S. C. Gordon, of Portland, Me., stated that out of eighty cases he had seen three of ventral hernia; he had operated in thirty-three

hysterical cases, and twenty-five would say to-day they were cured, which differed from other statements made.

Dr. Cowden stated that he himself suffered from invagination of the gut (referring to Dr. Senn's paper), but the finger inserted into the bowels could just reach it; after days of suffering a long rubber tube was inserted into the rectum, and a large bottle of water secured at the other end and gradually raised; suddenly there was a sharp report and the abdomen was distended. The speaker thought the gut had been ruptured, but the invagination had been reduced, Dr. Senn's proofs upon dogs notwithstanding.

Dr. T. G. Richardson, of New Orleans, remarked that his experience in these cases was that the percentage in the negro was in excess of that in the white man.

Dr. Donald Maclean, of Detroit, Mich., read a paper on **three Cases of Surgical Disease of the Kidney, with an Account of Operations Performed for their Relief, the Complications which arose, and the Results.** The first case mentioned was that of a woman, twenty-one years of age, who was supposed to be suffering from an ovarian tumour. Laparotomy was performed. The patient entered the hospital in October, 1884, and in January, 1885, was perfectly well. The second case was a woman, forty years of age, the same result being secured; all trace of kidney-tissue had disappeared in the immense cyst. The third case was a child, twenty-two months old; this case resulted fatally.

The next paper, by Dr. Neudörfer, of the Austrian Army, entitled, "On the Present Stand-point of Antisepsis and the Best Mode of its Application in War," was read by title, after which an instructive paper, by Dr. B. A. Watson, of Jersey City, on the **Primary Treatment of Gunshot Wounds**, was read. The author first adverted to the requisite qualifications of a military surgeon, and the duties required of him; discussed the selection of a proper site for a field station, and the means which should be adopted primarily for the arrest of hæmorrhage. As the ligation of arteries is only, under the circumstances, exceptionally required, compression should be relied on to control hæmorrhage. The author urged the importance of removing all foreign bodies from the wounds, and advocated the occlusion of the wounds of entrance and exit with aseptic bandages and compresses. Thoracic and abdominal wounds cannot be treated at the field station, and should be removed from the scene of action as rapidly as possible. Bayonet wounds should be treated in the manner suggested for gunshot injuries, while wounds produced by large projectile fragments of shells, and the like, should receive the treatment usually recommended.

Dr. W. N. Hingston, of Montreal, Canada, discussed Dr. Maclean's paper. He remarked that he agreed with him in all but one thing—viz., regarding abdominal section. He had operated in three cases; in two of these cases he had made the abdominal section, and both patients died from the shock. In the second case he performed the lumbar incision and the patient survived, and there was but little disturbance of the system after the operation. The speaker considered the lumbar incision advisable in all cases where possible.

Mr. Edmund Owens, of London, England, thought there were three factors which should guide us in the operation. If there was a doubt about the operation, it should be done through the abdominal wall. Again, the size of the tumour must be considered, and in what line of the profession is the operator called, gynecology or surgery. This latter will often decide the point according to the ground he is apt to go over.

Dr. Hardy, of Indianapolis, mentioned a fatal case where the median incision was made.

Dr. F. Lange, of New York, used the lumbar incision; and if the tumour was too large to be removed, he thought it a good plan to incise it and perform a second operation when it had been reduced.

Dr. Maclean, in conclusion, remarked that perhaps he was not quite understood, as he had distinctly stated in his paper that where the lumbar incision could be performed it was preferable. In the cases he mentioned he had no choice. His first case the speaker thought was an ovarian tumour, and naturally made section in the median line.

Dr. Richardson, of Boston, read a paper on **Gastrostomy for Foreign Bodies in the Throat.**—A patient (male), thirty-seven years of age, was presented to the Section, from whom the doctor had removed a plate with four teeth attached from the lower portion of the œsophagus, about one and one-half inch from the stomach-entrance, by performing gastrostomy. When first seen by the doctor he could discover no obstruction, but the man was, however, retained in the hospital. He was finally discharged apparently well, the pain at the point indicated by him having subsided, and he was able to eat his meals. Eleven months later he returned very much emaciated, the pain returning and being much more severe, gastrostomy was decided upon and the operation performed, the opening being made large enough to admit the hand; the plate was then discovered in the location

stated. Owing to its long retention a small abscess had formed there, which subsequently ruptured, the patient making a rapid recovery. The speaker remarked that had he been certain the plate was there, he was positive he could have removed it with the forceps; but the difficulty lies in locating, and also the location of the cricoid cartilage and the cardiac opening. He had operated in sixty cases, and found the average distance from the incisors to the cardiac opening to be fourteen and one-half inches; the longest was seventeen inches, and the shortest ten and one-half inches. The writer described accurately, on the black-board, the anatomy of the parts and location of the plate removed; showing that by gastrostomy or œsophagotomy the œsophagus would be reached at all points with ease.

Dr. F. S. Dennis, of New York, read a paper on **Amputation of the Hip-joint for Sarcoma.**—The case was quoted in order to induce surgeons to report such cases and the results. Out of twenty-eight cases of sarcoma of the thigh, only two were living. The case at present was a young man seventeen years of age; family history was excellent. Five months before entering the hospital the swelling in the left thigh commenced; it had been aspirated, and ten ounces of fluid removed. The tumour when seen was ten inches in length, and twenty-seven in circumference, the inguinal glands were slightly enlarged. The diagnosis of sarcoma was made, and amputation at the hip-joint was decided upon. No elastic bandage was applied to the leg, but a strong rubber band was passed around the thigh above the joint, which controlled all hæmorrhage, and the operation was a bloodless one. On the sixth day the dressings were removed, and the wound was found to have united by first intention; temperature did not rise over 100°, and only reached that point on one day. The points worth noting are:—(1) this patient had a sarcoma, with no hereditary taint; (2) there was no exciting cause; (3) the great rapidity of growth; (4) absence of metastasis; (5) rapid return to health, as the boy is perfectly well now; (6) importance of secondary hæmorrhage; (7) unfavourable prognosis in his condition; (8) the diagnosis was confirmed by the microscope in the hands of Dr. Grower; (9) abscess limited to shaft of bone; (10) absence of a spontaneous fracture of the femur; (11) large size of the mixed cells of the sarcoma; (12) radical removal of the tumour by amputation at the hip-joint, not at the upper third of the thigh.

Dr. Garmody, of New York, read a paper on **The Surgical Treatment of Traumatic Insanity by means of the Trephine.**—The speaker reported the case of a young woman who was struck on the head with a brick, causing depression of the skull; she had been trephined shortly after, but ten years later she began to exhibit symptoms of insanity; trephining was suggested by the speaker, and the operation followed out, the space after the operation being three and a half inches by two inches. No elevation of temperature followed, and at the end of twenty-one days she was perfectly rational; the wound united by first intention.

Sir James Grant remarked that the case was an interesting one, and in his experience of brain surgery he had found that the lower type of brain would bear a fracture of the skull much better than those of an intellectual type. He quoted the case of a mill-hand who fell out of a window and fractured his skull. The speaker was sent for, and on his arrival found the man walking about, and yet there was a depression in which the finger could be inserted; the brain he considered became very sensitive in educated individuals.

Dr. Burney read a paper, on behalf of Dr. Richardson, of St. Louis, on a case of **Gastrostomy for the Relief of Foreign Bodies in the Throat.** The speaker also mentioned a case in which he himself had operated, a man having swallowed an ordinary plated case-knife (the latter he presented at the meeting). While playing with his family the knife slipped from his fingers as he pretended to swallow it, and really did. The writer did not believe in the continued suture in this operation, but the interrupted, one and one-eighth of an inch apart.

Dr. Manley, of New York, read a paper on a case of **Gun-shot Wound of the Large Intestine, with a Successful Result by Laparotomy.**—The patient was operated on twice. The speaker considered that opening of the peritoneal cavity of a man was far different to opening that of a woman, and liable to more risks; the breathing of a man is largely abdominal, while that of a woman is almost entirely thoracic; the incision in the man should not be a bit larger than is necessary, because of his labourious work being liable to produce ventral hernia after recovery. For exploratory operations he made the median incision, but thought there might be exceptions to this rule. In regard to the drainage-tube in these gunshot wounds of the abdomen, he thought there was no need of them when the peritoneal cavity was healthy and laparotomy performed soon after the injury, and although he had put one in in the case spoken of, he should not do it in the next one. Of course there might be exceptions, but he believed the tube was a source of irritation and more liable to produce hernia.

Dr. Robert Newman, of New York, read a paper on the **Use of the Galvano-Cautery Sound**, particularly in hypertrophy of the prostate gland, with report of cases. The application of the cautery, he stated, would depend much on the condition of the patient, but it averaged about from every three to six days; the cautery was not to be red hot, but simply to show a bright light. The apparatus was exhibited to the Section. The advantages claimed are that there is no hemorrhage, the healing is more rapid, and there is no septicæmia. Out of these cases ninety-one per cent. are made comfortable and given a new lease of life.

Dr. Carnochan, of New York, presented a remarkable specimen of **Bony Union of the Neck of the Femur within the Capsule**, after fracture, occurring in a woman seventy years of age. As she had plenty of means she had every attention. She was kept in her fracture-bed for nine months, rest being the method of treatment. The value of the specimen was very great, especially in courts of law.

Dr. F. Lemoyne, of Pittsburg, presented some drawings of an united fracture of the femur, and history of a successful case in which he had applied his method of treatment—viz., **Double Splice and Wired Clamps**.—The treatment has been successful in three cases—two of the humerus and this one of the femur. The bone was cut down upon and the fragments found to be overlapping nearly three inches. The ends were sawed off, the upper fragment in the form of a wedge; from the lower one a wedge-shaped piece of bone was removed, so that the upper fragment fitted into it. A hole was drilled in both bones about one and a half inches from the fractured ends. A stiff, flat, steel bar, with a prong at either end, was placed lengthwise on the surface of the bone, so that the prongs were inserted into the holes; a stout piece of wire was then passed around the clamp and femur at either end, and twisted close up, holding the clamp in position. The wires and clamp remained there nine weeks, when the wound was re-opened and the clamp removed. The bone was firmly united, but the limb is two and a half inches shorter.

Dr. Manley, of New York, stated that he had had considerable experience in wiring bones, and thought the bones when lapped very much should be wired at the first; the wires he always left in, as they did no harm. In one case of compound comminuted fracture he had followed this method and secured perfect union.

Dr. Quimby, of Jersey City, stated that he could hardly approve of this method.

Dr. Lemoyne remarked that he thought his method was original, and previously everything else had failed, the man having undergone a number of operations prior to his treatment, and all of his cases so treated had met with success; he did not believe in wiring in primary fractures.

Dr. Gibson exhibited some wire extension splints for fractures at or near joints; he had used them since 1879.

Dr. George Assaky, of Bucharest, Roumania, read a paper on **Iodol in Surgery**.—The conclusions arrived at were: (1) Wounds unite under iodol by first intention. This union, however, being the result of various and complex conditions attending operation, it is not possible to attribute to iodol alone the absence of suppuration and inflammatory conditions. In wounds which gape and suppurate iodol is an excellent antiseptic. It rapidly retards suppuration, renders it inodorous, reduces the frequency of dressing, and considerably hastens cicatrization. In ulcerating or gangrenous wounds iodol aids in resisting the destructive process, and changes the wound, after a variable time, to a healthy, granulating condition. This action of iodol extends itself to hard chancres. In cases of soft chancres the result is variable. Sometimes it transforms them into a simple wound with brief delay; at others it is insufficient for this purpose, and it becomes necessary to employ in addition, locally, antiseptic lotions. The same is true with reference to open venereal buboes of the groin. The powdered iodol has this advantage over iodoform, that it is free from odour and is not toxic in its effects. (2) Doses of iodol of from 0.40 centigrammes to 2.0 grammes, daily, produce no functional trouble, even if continued a long time. These doses give marvellous results in tertiary syphilis and in scrofulous affections. In the secondary stage of syphilis, taken internally, it rapidly destroys the syphilitic manifestations. Iodol seems to aid the general nutrition and increase strength and flesh. It is indicated in all cases of specific malnutrition. Iodol is an antipyretic. In acute infectious diseases, such as erysipelas, etc., it causes a rapid fall of temperature.

Dr. Milton J. Roberts, of New York, read a paper on **A New Method of Operating on Bone by means of the Electric Osteotome**.—The speaker presented an elaborate apparatus for this purpose, of most ingenious mechanism. One member remarked that he feared such a display would make the patients feel rather nervous, if seen by them. The osteotome consisted proper of a hollow cylindrical handle, protruding from which was the shaft of the instrument, at the end of

which was a small wheel with teeth like an ordinary finger-saw; the base of the handle was connected with the electric batteries by means of the covered wires usually used in all electric batteries; anterior to the handle were "cut offs," which could be worked by the forefinger and thumb, disconnecting the current in an instant, and checking the revolutions of the saw-wheel just as quickly; according to the diameter of the bone, different-sized saws were adjusted. In connection with this was a set of drills for drilling into any part of a diseased bone and removing the sequestrum or dead tissues in the bone cavity, the cavity being illuminated by a small electric light thrust in at different stages of the operation in order to secure removal of all carious bone. The femur was exhibited, the head of which had been drilled in this manner, the drill-opening into the bone being three-eighths of an inch in diameter, while the entire inside portion had been removed by the drill. The question was raised as to the cost of such an apparatus being beyond or more than the surgeon would care to invest unless making a speciality of such diseases, and one gentleman affirmed that he could perform all the work which this instrument did with the regular dental drill, and that he had done it on several occasions, borrowing the drill from a neighbouring dentist.

Dr. Close, of Illinois, thought the chief advantage of the apparatus was that the operator does not necessarily require skilled assistance, as the current was controlled by the hand in which the instrument was held, while the left hand was at liberty. He had been in the habit of using at times the band-wheel engine for such purposes, but found it too slow; in order to cut bone the saw must revolve quickly in such an apparatus.

Dr. Roberts, in conclusion, said that he had tried the dental engine many times and found the revolutions too slow, and it was for that reason he had set to work in order to secure the best possible method of moving bone in such cases; when the wheel revolves slowly the bone-tissue is torn; had it been satisfactory, he would not have spent the time and money in bringing forward a new instrument. In operating, the periosteum is not lifted or removed, but cut through with the bone. The speaker also exhibited, some instruments for measurement, which would record the exact size of the bone to be removed in cases of deformities, etc.

Dr. Moore, of Richmond, Va. (Section of Military Surgery), after a few preliminary remarks, read his paper, entitled on the **Treatment of Penetrating Gunshot Wound of the Abdomen**. The author gave statistics of cases of this nature and the rate of mortality, and quoted at length from reports of the French and British army. No surgeon had, in his opinion, had sufficient experience with this operation, which was comparatively a new one, to be considered an authority on disputed points. He spoke of the difficulties of diagnosis of perforation, and advocated the exploration of the wound with some delicate instrument. The incision should be made only sufficiently large to allow a thorough exploration, and the earlier after the reception of injury, barring the occurrence of shock, the greater were the chances for recovery. It is the opinion of Sir William Malcolm that if the operation be delayed twenty-four hours no case ever recovers. In conclusion, he advocated supporting measures and the use of quinine hypodermically previous to the operation, to diminish the liability of resultant shock.

Dr. Varian's views were in harmony with those of Dr. Moore so far as civil practice is concerned, but the question still to be discussed was the treatment of such cases upon the field of battle.

Dr. Watson, of Jersey City, agreed with Dr. Morton.

Dr. Bentley, of Little Rock, Ark., dissented from the opinion of Dr. Morton, and regarded the application of the method of treatment as impossible on the battle-field, as it is an operation which requires skill, time and care. He, however, recognized its value in private and hospital practice, where all the conditions are favourable.

Dr. Carnochan, of New York, presented a specimen of **Double Dislocation of the Hip-joint**. He remarked that previous to 1820 this condition was unknown, but in 1826 Dupuytren first brought it to the notice of the profession. The speaker stated there were various theories as to the causation of this condition, among which were carelessness of the accoucheur, movement of the foetus in utero, etc.; the question arises, also, as to whether it is really a dislocation or a malformation.

Dr. R. T. Morris, of New York, stated that he did not think that it could be caused by careless handling of the physician, as in the northern part of Germany it was quite common, and they certainly had skilled physicians there. He thought it might be due to arrest of development.

Dr. Post drew attention to the two classes of cases, one of which seemed to be rachitic; but he had seen it occur in healthy infants with a difference in length of limbs. A few weeks since he saw a case in which the head of the bone was in the thyroid foramen; the speaker could only account for it that the child moved in utero.

Dr. Henry James, of Waterbury, Vt., read an important paper, giving the results of his experience during the late war, with **Gun-shot Fractures of the Femur**.—The author's conclusions upon this interesting subject are based upon the results of no less than 427 cases occurring in his service, and treated by himself, or under his immediate observation, in two field hospitals in his charge during the year 1862 and 1863. Of these fractures 95 were in the upper third of the bone, all of which were treated conservatively, giving a mortality of forty-six per cent. at last reports; 125 were in the middle third, 102 of these being treated conservatively, with a mortality of thirty-two per cent.; 23 were amputated, mortality forty per cent.; 207 cases were in the lower third of the bone; 67 of these, not including knee-wounds, were treated by the conservative method, with a mortality of twenty per cent.; 140 cases were amputated, resulting in a mortality of thirty-five per cent. Besides these 427 cases, there were 34 fractures involving the knee-joint, treated conservatively, with a mortality of eighty-five per cent. The cases requiring amputation terminated earliest, but about one-eighth of them suffered from painful and tedious osteitis. Up to about forty years of age, advance in life did not seem to increase the rate of mortality. The author's conclusions are the following:—Antero-posterior wounds did no better, in his experience than the transverse. Fractures caused by bullets moving with great velocity were fraught with more danger than those moving at a lower rate of speed. Wounds occurring in prisoners did not do so well as those in their captors under the same conditions; this was probably due to the incident moral influences. Gun-shot fractures sometimes united as readily as simple fractures. False joint occurred but once among the two hundred and sixty-three cases treated conservatively. Secondary hæmorrhage occurred only in nine cases, in several times it was incident to septic poisoning. Tetanus only occurred once. Hospital gangrene seemed to be induced in the autumn of 1863 by bad ventilation and the occurrence of cold, damp weather. The shortening, in the cases which completely recovered was generally of more than one inch; it was, in several instances, increased by the too early use of the limb. The formation of callus was sometimes so irregular and excessive in amount as to impede muscular action; it sometimes encroached upon an artery or nerve and caused secondary hæmorrhage or neuralgia. In some cases the callus was absorbed in the course of septic inflammation. Refractures, caused by falls and similar accidents, generally reunited readily when the wounds in the soft parts were healed. The limbs often became much more useful than any artificial substitute; the author has unfortunately no statistics bearing upon this subject to offer. Regarding the treatment of injuries of this nature, he would enjoin the surgeon *not* to saw off the ends of fractured bones, and not to use too much force in tearing off fragments of bone still attached to the periosteum. Moderate, simple extension by the weights and pulleys is the best in the majority of cases; in some of the cases that did the best no extension was used. He would advise the dry dressing of wounds, with plenty of absorbents, rather than with water-dressings. Strict antiseptics, according to the modern idea, is impossible in large hospitals on the battle-field. In conclusion, the author spoke of the necessity of a liberal diet, the intelligent use of stimulants, and due regard to the sanitary precautions in the camp or hospital in which this class of injuries are treated.

Dr. Robert Reyburn, of Washington, desired to know what proportion of the doctor's cases had been treated in tents and in buildings.

Dr. James said the majority of the cases were treated under canvas, with free access of air; with the advent of the cold and damp weather of winter, the ventilation was not so perfect, as it was difficult to impress upon the soldiers the importance of free ventilation, at a time when they were suffering from the cold. It was, as previously stated, at this time that hospital gangrene set in.

Dr. Reyburn said, in my experience, the kind of hospital in which the wounds under consideration are treated has much to do with the mortality; the treatment in tents I consider the best; unfortunately, most of the cases observed by him in the service could not be treated under such favourable conditions, and he had to report a mortality of about seventy-five per cent. The results achieved by Dr. James were most remarkable, and show what can be done by conservative surgery.

Dr. E. Griswold, of Sharon, Pa., who read a paper entitled **What Conditions on the Field Justify Amputations in Gun-Shot Wounds?** The author claimed that amputation on the field of battle cannot always be done, although the established rule of surgery, as well as the opinion of the surgeon, may demand it in many cases in which it is not done. The exigencies of war often separate the surgeon from his equipments and deprive him of the means of action, or he may be over-worked and unable to attend to his duty. The surgery of to-day and of the future makes it necessary for military surgeons to be supplied with means by which æssepis can be practised upon the field in the treatment of wounds, and this can be done and made practical wherever an adequate supply of water is attainable, if a rapid method of filtration

and purification is available. The possibilities of antiseptic surgery are already largely developed, and the military surgeon of the future must know what it is to be expected in the way of conservatism; and when his patient, having a severe gun-shot wound in one of his extremities, is found to be clearly beyond the reach of conservatism, he is not only justified in amputating in the field, but it is his bounden duty to do so.

Dr. Bontecon said he would practise conservative surgery when there are arteries to nourish the limb and veins to carry the blood back from the injured member to the heart.

Dr. E. A. Wood alluded to other elements, such as shock, which must be taken into consideration in determining whether amputation be or be not required, and in some instances of probable deformity resulting, with consequent uselessness of the limb, the part should be excised.

Dr. Collins, of Pennsylvania, thought many cases that would otherwise recover died of the wear and tear incident to the transportation.

Dr. H. H. Biedler, of Baltimore, Md., adverted to certain operations for grave injuries having terminated fatally after amputation, from the operation itself, and without the complication of shock.

Dr. Griswold closed the discussion by saying that he had noticed that shock, in injuries of the knee-joint, seemed to be more serious than in those of the hip-joint. When the injury is such that amputation is clearly indicated, it should be done early: still, even in bad cases, conservative surgery was available, and an attempt should always be made to save the limb.

(To be continued.)

The Spirit of the Societies.

LEICESTER MEDICAL SOCIETY, January 13th. **Small-pox in Montreal.** By H. TOMKINS, M.D., B.Sc., Medical Officer of Health, Leicester.—From particulars obtained during a recent brief visit to Canada I have been able to bring before you an account of the terrible epidemic of small-pox which overtook Montreal in 1885-86. The origin of the outbreak was a conductor of a Pulman-car, who came from Chicago on the last day of February, 1885, suffering from a very mild attack of small-pox, and which was thought to be chicken-pox. He was treated in a large general hospital (the infectious hospital being at the time closed), and here the disease spread to a number of the other patients, etc. It was then decided to send all the patients to their homes in order that the building might be thoroughly disinfected. This step proved to be an unfortunate one, for amongst the 200 patients thus scattered in all directions, numerous other cases arose. For some years prior to this time Montreal had been free from small-pox, and owing to a certain amount of opposition, vaccination had not been enforced, with the result that a large number of parents had neglected to have their children vaccinated who were not opposed to the operation. Becoming thus planted in a susceptible population the disease rapidly spread, and owing to the absence of the notification of infectious disease, the health authorities were not made aware of all the cases that arose, and this also favoured its spread. By July the popular mind was becoming alarmed. Powers were obtained for enforcing notification of disease as well as vaccination, and large sums of money were spent in providing hospital accommodation, etc., and offenders were rigorously dealt with by the law. Among a certain section of the community these measures were at first opposed, and after a patient had been compulsorily removed to hospital who was in danger of spreading the disease in a thickly-populated community a riot arose, and considerable damage was done to various municipal and other public buildings. This, however, was soon subdued, and the people made to understand that the law must be obeyed. So rapid, however, was the spread of the epidemic, that by the end of the year no less than 3,164 deaths had taken place—a mortality surely unknown in any recent experience of this plague. Vaccination was now eagerly sought for, and so great were the crowds besieging the vaccination stations that the police had to be employed to regulate the traffic and maintain order. No less than 80,000 vaccinations were now performed in a population of something over 160,000. The following figures are instructive:

Of the 3,164 deaths there were	{	531	under 1 year of age;
		1,505	1 to 5 years of age;
		681	5 to 10 years of age;
		447	over 10 years.

3,164

So that there are 2,717 deaths of children under ten years of age, the very age at which, in properly vaccinated communities, the smallest number of deaths always occur. The figures from the hospitals are likewise most instructive. 1,332 patients were treated there, of whom 418 died, equal to 31.3 per cent. Of these 805 were not vaccinated, and 527 vaccinated. Of the 805 unvaccinated there died 315, or 39.1

per cent.; of the 527 vaccinated 103 died, or 19.5 per cent. And again, as showing how much more severely the children suffered, the following should be noted: Of the above 1,332 patients, 489 were under ten years of age, and 843 above that age. Amongst the 489 there occurred 202 deaths, while amongst the 843 only 216 deaths were recorded. What the cost of this epidemic to Montreal was can only be guessed at: loss of business, loss of health, expenses of sickness and death, etc., were all great; but the Health Committee alone spent some £36,000 in coping with it. The death-rate of the city, which averaged 26.7 per 1,000 in the five previous years, reached the enormous figure of 46.7 per 1,000, and the deaths exceeded the births by 1,522—a complete reversal of figures from ordinary times.

The lessons that may, I think, be learned from this outbreak are, that, given a susceptible material—i.e., an unvaccinated population—and small-pox once started therein has lost none of its old powers to maim and to slay. Secondly, there is demonstrated the absolute importance of some law being in force by which prompt notice of such diseases shall be made to the proper authorities; and thirdly, that there shall always be ready, without delay, good and sufficient accommodation for separating, when necessary, the infected person from the rest of the community, with compulsory powers to enforce removal when necessary, together with efficient disinfection or destruction of infected material, etc. Montreal has become wise by bitter experience, and to-day compulsory vaccination is in force, and the opposition to it has diminished to very small proportions; and in all cases where it is desired calf lymph is used by the public vaccinators. Compulsory notification of infectious disease is likewise in force, and proper hospital accommodation is available without loss of time. In the face of the evidence supplied by this outbreak, of the susceptibility to and mortality from small-pox in an unvaccinated population, surely a heavy weight of responsibility attaches to those agitators in this country against vaccination, influencing as they do chiefly the poorer and less educated classes, who are least able to form a right judgment on such a question for themselves, and who in all outbreaks of contagious disease suffer the most severely. Sheffield, a town much larger than Montreal, is to-day suffering from an outbreak of small-pox, but the mortality, especially among the vaccinated and among the children, is trivial when compared with the above.

At present no English community, not even Leicester, has in it so large a proportion of unvaccinated persons as Montreal had, and therefore are at present much more largely protected than that city was. It is only the last two or three years that the vaccination laws have not been enforced within this borough. When sufficient time has elapsed, as at Montreal, and the unvaccinated of the town shall become numbered by tens of thousands, a like catastrophe is only too possible, and those who are best familiar with the power of this disease to disfigure and destroy can but look forward to the future with the gravest apprehensions. Whether then, or for how long the present measures adopted here, admirable in themselves and highly to be commended, as far as they go, will suffice to keep the enemy from our doors, time only can show.

OBSTETRIC SOCIETY OF PHILADELPHIA.—At the last meeting of this Society Dr. HAMILTON recorded a case of **Puerperal Malaria Fever simulating Sepsis**. Pus and albumen were found in the urine of a young woman. An answer to the following questions was desirable:—(1) Was the right kidney chiefly affected, or was the pain on the right side referable to a morbid condition of the left kidney? (2) Were both kidneys diseased, or was one healthy? (3) Did the pus really come from the kidneys, or was it confined to the bladder? He was able to obtain an answer by the use of Dr. Kelley's urethral catheters.

Dr. SCHIEDT read a paper on the **Delivery of the after-coming Head**. He is of opinion that forceps constituted the best, quickest, and safest treatment.—Dr. WILLIAM GOODELL said the forceps was the only proper aid in the expulsion of the after-coming head.—Dr. M. PRICE said he made it a rule to have his forceps ready in breech deliveries.—Dr. LONGAKER said the forceps should be in readiness to apply as soon as the body had escaped from the vulva.—Dr. NELSON said he was as strong an advocate of the application of the forceps to the after-coming head as any man could possibly be.—Dr. J. C. MORRIS said the forceps should always be at hand, and there was no difficulty in putting them on.

PHILADELPHIA COUNTY MEDICAL SOCIETY.—Dr. E. J. BRUEN reported some cases of **Laparotomy for Tubercular Peritonitis; Pulmonary Cavity treated by Incision; Abscess of the Liver**. The first patient died nine days after the operation, the last patient on the following day. Dr. Bruen said that the liver can be safely explored with a moderate-sized aspirator needle, and that he had frequently practised this method in doubtful cases without any unpleasant consequences.—Dr. OSLER said that in these cases of abscess of the liver we should, if possible, arrive at an accurate opinion of the etiology of the abscess. To explore the liver thoroughly in a case of multiple abscess is a hopeless procedure.—Dr. W. H. PARISH said he had had no experience in exploring the liver for pus, but he would hesitate a long while before

accepting the statement that it is safe to explore an abscess in any organ where it was necessary to pass the needle through the peritoneal cavity. The thrusting of an aseptic needle into healthy liver tissue is, however, doubtless quite safe.—Dr. ROBERTS said he scarcely thought that tapping of the liver was such a dangerous procedure as would be indicated by the remarks of the last speaker. If he had a case of suspected abscess of the liver, he should introduce an aspirating needle in various directions with a great deal of certainty that he would do no harm.

SURGICAL SOCIETY OF PARIS.—At a meeting of this Society on December 21st, M. TERRILLON communicated a **New Series of Thirty-five Ovariectomies**, with four deaths. These patients died from causes apart from infection or peritonitis. M. Terrillon said he had often operated under conditions most discouraging, but had attained, nevertheless, unhoped for success. He condemned the spray as useless and even dangerous. He had discarded the ordinary sponge, preferring the tissue sponge used in Germany. Lavage of the peritoneum with warm water was indispensable in complicated cases, and he regarded the same as essential to obtain speedy action of the bowels. [It would appear that M. Terrillon has been reading with advantage Mr. Lawson Tait's papers.—*Reporter*.]—M. TRELLAT did not think it necessary to go to Germany for the sponges, as he used an artificial sponge, made of cotton gauze, rendered antiseptic by steeping in a solution of bichloride of mercury.—M. POZZI preferred a vegetable sponge, and he also thought it an excellent plan of purging the patients.—M. LUCAS CHAMPIONIERE said he always used the ordinary sponges with large cells. He saw no advantage in using artificial sponges.

CHICAGO MEDICAL SOCIETY.—At a late meeting of this Society Dr. JAMES H. ETHERIDGE narrated four cases of vaginal hysterectomy.

Case 1.—S—, æt. forty-seven, mother of nine children, with epithelioma of the cervix. Died from exhaustion in forty-five hours. "The autopsy revealed a small rent in the bladder, which was concluded to be the cause of the peritonitis."

Case 2.—C—, æt. thirty-six, small epithelioma of the cervix. In thirty-six days she left the hospital.

Case 3.—C—, æt. forty-nine, epithelioma of the cervix.

Case 4.—Incoercible hæmorrhage from a small fibroid in the posterior uterine wall. Doing well twenty-one days after operation.

In these cases hæmorrhage was controlled by Sweb forceps.

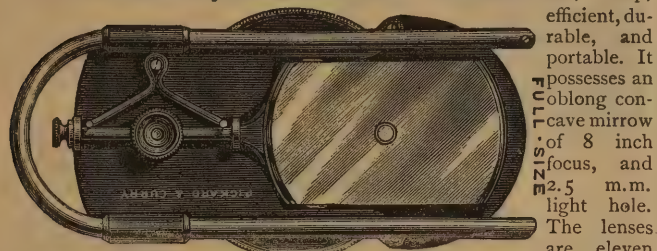

Dr. C. T. PARKES: I am very much pleased with this paper, in that it introduces a method of controlling hæmorrhage that has been satisfactory to me a good many times. We are indebted to Péan, of Paris, for this method. He depends upon it on all occasions and in all operations. It is not an unusual thing to find a wound that he has made containing a dozen of these forceps. He never uses a drainage tube. After seeing it done by him, I have resorted to the use of the forceps as a means of hæmstasis in all operations where it was difficult to apply a ligature, and especially in removal of carcinoma of the rectum. Anyone who has performed that operation knows how difficult it is to apply a ligature that can be trusted, high up in a wound so small as that made in the removal of a carcinoma of the rectum. And on several occasions I have left half a dozen forceps, removing them in twenty-four hours, without subsequent trouble. It saves a great deal of time, and is perfectly reliable. I do not think it is necessary, on all occasions, to leave the forceps on forty-eight hours. I think that after squeezing with the large jawed forceps for twenty four hours, there is scarcely any danger of hæmorrhage from a vessel the size of those that are included in it, and by diminishing the time of the retention of the forceps you reduce the danger of necrosis of the tissue contained in the forceps. Another point, I don't see the necessity of turning the uterus over, thus endangering the entrance of diseased tissue into the peritoneal cavity. The posterior wall is uncovered, the broad ligaments are exposed, and what is the use of turning the uterus over? These forceps will reach the top of it, and they will include the broad ligaments on either side, and they can be applied just as well with the uterus in position as if it were turned over. There is great necessity of keeping close to the uterus with the forceps. I think there is more danger with the use of the forceps, in including the ureter, than we are aware of, and if the operation is done where there is any probability of recovery, it does not do any harm to keep well up to the uterus. If the tissue is diseased beyond that point you might as well let the patient alone.

Dr. D. T. NELSON: I wish to quote a word from Martin, of Berlin, spoken before the International Congress, where this subject was discussed quite fully. He advocates the operation strongly, and made this important point, which I think was not too much emphasized by the reader of the paper, that the operation is not justifiable when the uterus is not movable. When the tissues above and about the uterus have become involved by the diseased condition, then the operation should not be done. Martin's later operations have been only upon this class of cases, and consequently the promise of success—permanent cure—has been far greater than it would otherwise be.

Surgical Aids and Appliances.

81.—A NEW OPHTHALMOSCOPE.

DR. WALTER H. JESSOP has devised a new instrument, cheap,

efficient, durable, and portable. It possesses an oblong concave mirror of 8 inch focus, and 2.5 m.m. light hole. The lenses are eleven in number, and comprise $\times 1 D$, $\times 2 D$, $\times 3 D$, $\times 4 D$, $\times 9 D$, $\times 20 D$; forestimating by the direct method most cases of refraction. The lense $\times 9 D$ is for the direct examination of the vitreous and lens, and $\times 20 D$ for that of the iris, anterior capules of the lens, anterior chamber, and cornea. The lens $\times 6 D$ can be replaced, if desired, by one representing the observers refraction.

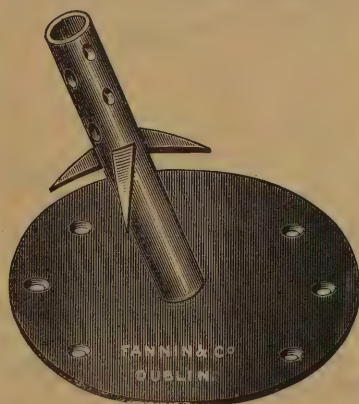

82.—NEW FIXATION FORCEPS.

THIS is also the invention of Dr. Ward Cousins, and the engraving exhibits its size and construction.

83.—A NEW DRAINAGE TUBE FOR EMPYEMA.

DR. FRANCIS J. HEUSTON, Dublin, has brought out a new drainage tube. It is about three inches in length, and has a very large flange composed of soft material, which hinders the tube

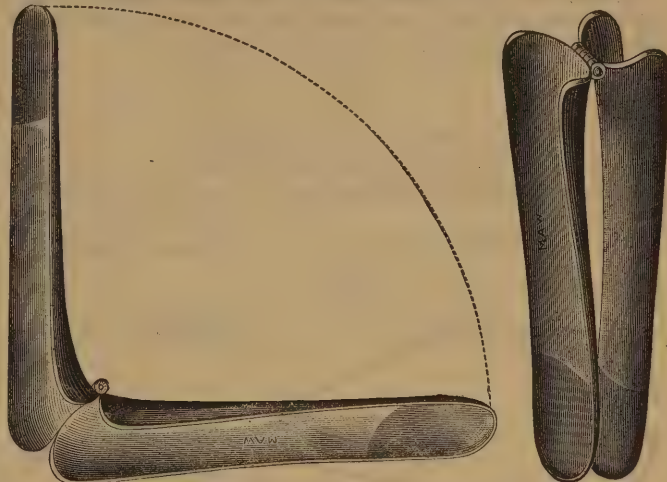

from passing within the thorax. About an inch internal to the flange are placed three wings, which hinder the expulsion of the tube by the patient's respiratory efforts. The tube is made of different diameters and length.

84.—A NEW SURGICAL NEEDLE.

DR. JOHN M. H. MARTIN, Blackburn, has made an improvement in surgical needles. The eye is fixed at right angles to the body, and close up to a shoulder on each side, so that silver wire or other material passes readily through without any hitch.

85. NEW VAGINAL SPECULA.

MR. SMYTHE'S. — The accompanying illustration shows Mr.

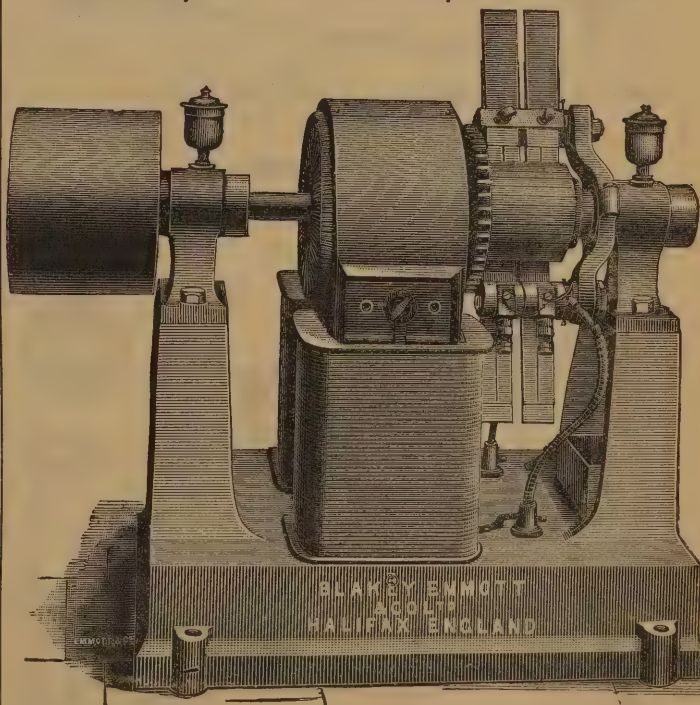

Butler Smythe's instrument open and shut. Its extreme portability is apparent.

DR. FLOYER's Vaginal Speculum consists of two valves and a coggled bar.

86.—DYNAMO FOR SURGICAL PURPOSES.

At the Ninth International Medical Congress, Dr. T. H. Martin, Professor of Gynæcology, Chicago Polyclinic, read a paper on "A Modification of Apostoli's Method." In the course of his paper he exhibited a new form of dynamo to take the place of the ordinary batteries in use. We have shown the drawing, as in the *Medical Record*, to a practical firm of electricians, and they are prepared to make their own dynamo in such a size and style as to meet all the

requirements of practice, and to have such armatures as will generate two distinct currents. For hospitals the dynamo is particularly suited, and it promises to be a very useful addition to the armamentarium of the gynæcologist. The drawing shows the shape of the Blakey Emmott Dynamo, which they are willing to supply to any hospital-electrician for trial on very liberal conditions.

87.—IMPROVED BINAURAL STETHOSCOPES.

1. DR. KERR, Bath, has devised a new instrument, consisting of two short metallic ear pieces, and a chest piece, connected by gutta-percha tubing fifteen inches long. It is cheap and portable.

ARNOLD'S STETHOSCOPE.

2. MESSRS. ARNOLD AND SONS have brought out a new single binaural differential stethoscope, percussion hammer, and pleximeter

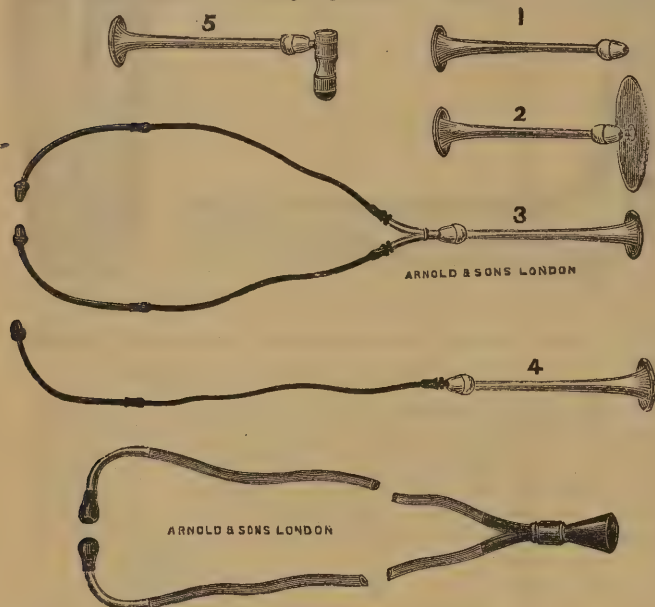

plate. It is called Pickering's "Panarkes" Stethoscope.

BATTEN'S STETHOSCOPE.

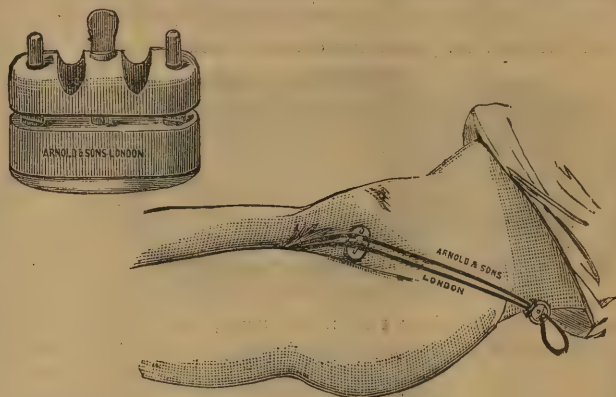

3. DR. BATTEN'S (Gloucester) Binaural Stethoscope consists entirely

of metal and vulcanite, and can be at once converted into a single stethoscope.

88. NEW PELVIC TOURNIQUET FOR AMPUTATION OF THE HIP JOINTS, AND OTHER AMPUTATIONS.

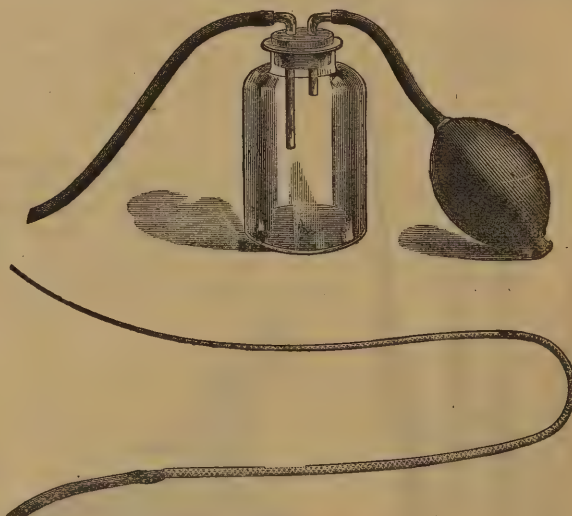

DR. WARD COUSINS has devised this instrument, which consists of

two parts, and which is a modification of his elastic cord tourniquet. The illustration explains its mode of application.

89. ASPIRATOR AND CAPILLARY CATHETER.

THE accompanying illustration shows Dr. Ward Cousins' Aspirator

and Capillary Catheter for retention.

Medical Miscellanea.

THE subject of our next illustration will be George Granville Bantock, M.D.

We shall publish in the March number an account of Woodhall Spa.

An American pharmacist states that there are 36,500 proprietary medicines in the market.

Mr. G. A. Philips, M.R.C.S., has been placed on the Peace for the borough of Walsall.

M. Pasteur has been awarded 12,000 francs by the Turin Academy of Sciences.

The *Blackburn Standard* is publishing a series of articles on the high mortality of that town. Such a step is needed.

A full-size copy of Rembrandt's "Lesson in Anatomy" has been presented to the College of Physicians of Philadelphia. Rembrandt was twenty-six when he painted this picture.

We congratulate Dr. Davy, Terenure, on the result of his trial. We trust that the prosecutor will be punished for perjury, and that some recognition may be made to Dr. Davy for his expenses.

We learn from the *Indian Medical Gazette* that the cultivation of ipecacuanha is making good progress in the Southern Presidency. Last year the number of plants increased from about 200 to over 700.

The St. Dalmas Plasters, Leicester, maintain their superiority in the medical market. Their bandages we have used for some time, and can confidently recommend them.

The *Lancet*, because it has 3,000 pages of advertisements, claims to be the representative organ of the profession. We have come to a pretty pass when such a plea can be urged as a claim to a first place in medical journalism.

Dr. H. Keane stated at the last meeting of the American Gynaecological Society that during the past eight years, 804 books and 7,505 journal articles and pamphlets have been added to the literature of gynaecology!!!

The Academia dei Scienza of Rome offers a prize of one thousand francs for the best essay on Embryology, which is open to universal competition. The essay must be written in Italian or Latin, and is to be presented on or before December 31st, 1888.

Reviews of the following books will appear in the March number:—Hime's "Home Education," Brundell Carter's "Ophthalmic Surgery," Bryant's "Diseases of the Breasts," Hutchinson's "Syphilis," Erskine's "Diseases of the Ear," Harrison's "Diseases of the Urinary Organs," McVail's "Vaccination Vindicated."

"In China," according to the *New York Medical Record*, "when a person who has been bitten by a mad dog begins to show signs of rabies, he is strung up by the hands and feet, and left in this comfortable position until recovery or death ensues. No better results are reported from this than from Pasteur's method of treatment."

We recommend to our readers Dr. Handford's "Graphic Charts;" they are very complete, and for hospital practice meet all the requirements of note taking. There is space for notes of cases, and on the chart the temperature, respiration, and pulse can be seen at a glance. Other details as to sputum, vomiting, urine, can also be noted.

Medical writers to the lay papers will have to be on their guard if the Royal College of Physicians, London, pass the resolution proposed by their Senior Senator—viz., "That no fellow, member, or licentiate should contribute articles on professional subjects to journals professing to supply medical knowledge to the general public, or should in any way advertise himself, or permit himself to be advertised in such journals." The College will have to make a clean sweep amongst its fellows.

The Cigars de Joy may be tried, to alleviate the painful attacks of asthma and bronchitis in cases that are beyond the reach of an entire cure, although in many instances they have effected the desired relief permanently. It is obvious that the directions given with them should be rigorously observed. We recently observed relief was afforded without the absolute suppression of stimulants, the quantity taken being reduced to about one ounce per diem. The length of time these cigars have been before the profession and the public serves to inspire confidence.

Mr. Kenneth Millican's Action *v.* Managers of the Queen's Jubilee Hospital has been disposed of. Mr. Millican was suspended from his position as Hon. Medical Officer at the public hospital owing to his taking office at another institution where homoeopathy was practised. Mr. Millican applied for an injunction, which was granted by Judge Manisty. The Court of appeal reversed the decision with costs. *Punch* has the following in reference to the correspondence which has taken place in the daily papers over the case: "Oh, dear!" exclaimed Mrs. Ram, "when are those letters on the Opium Medicum going to stop! I declare when I try to read them I get quite drowsy."

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "The Provincial Medical Journal," Horton House, Halifax.

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester; or to the London Representative, Mr. E. BELLA, 58, Charing Cross Road, W.C., to whom all communications respecting Advertisements should be addressed.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

WHAT ARE THINGS COMING TO?

To the Editor of "The Provincial Medical Journal."

SIR.—As a looker on, perhaps you will allow me to say a few words on medical attendance and providence, especially as I have for many years paid particular attention to the welfare of the working classes, and encouraged them to prepare for a rainy day, and to insure against sickness, disease, and death.—First, by foregoing self-indulgence in the way of drink and tobacco, and by judicious expenditure of their hard earnings in wholesome food and suitable clothing. Secondly, by joining some *bond fide* benefit society, such as the Standard Benefit Society, or the Hearts of Oak Benefit Society, to which no particular doctor is attached, and out of which they can go to what doctor they choose. Thirdly, by insuring their lives, as we know there are only two certainties in this life, viz., "Death and Quarter-day." An ounce of fact is worth a ton of theory. I will give one fact. I was apprenticed to a doctor in a provincial town, and had to make up the medicines, keep the books, and to attend to the surgery. Now the doctor had several clubs, some of which paid at the rate of half-a-crown per annum for each member. One of the influential members connected with one of his clubs paid that large (!) amount, who suffered from gout and its attendant physical evils, induced by over-feeding and indulgence in the flowing bowl. To my certain knowledge he was taking medicine for three years. He had on an average two bottles of medicine per week, besides pills, liniment, and lotions! He therefore swallowed at least three hundred bottles of medicine, and had in addition one hundred and fifty visits, and yet he paid the enormous sum of seven shillings and sixpence merely for the lot!

He was a respectable tradesman, doing a very good business, and no doubt congratulated himself on his business tact in getting doctored on the cheap. He could have well afforded to pay the small sum of one shilling for each supply of medicine, which in three years would have amounted to £15, and 1s. 6d. for each visit, which, with the charges for the medicine, would have amounted altogether to £26 5s. 0d. What chemist would dispense the bare medicines at so insignificant a rate?

Of course there are many grandees in the medical profession as well as among the working classes to whom such fees as I have named would be considered unprofessional, too low, &c., and yet these sticklers for professional etiquette would rather work at starvation rates, under a contract system, than get moderate and reasonable remuneration for actual work done.

If the ten thousand persons who belong to the clubs, benefit and dispensary associations of Gloucester, paid 4s. per annum, that would make £200 for each thousand members to be attended during their illness by the medical man, of which I am convinced half of the proceeds ought to be expended on drugs, surgical instruments, and other necessary appliances. Now it is generally considered that a thousand persons ought to be a large practice for a medical man, demanding his serious attention, and it is absurd to suppose the remuneration is sufficient for a man of ability and experience. To a working man health means wealth, and medical men are no more than men, and reward sweetens labour. I maintain human life is too precious to be cared for in this wholesale manner.

As education improves no doubt these evils will be somewhat mitigated.

As things are no wonder medical men as a rule die insolvent. If a medical man grows rich when his practice is confined to club patients, he does so at the sacrifice of his honour and integrity! I have heard some unprincipled medical men who have large club practices boast of the smallness of their drug bills, but thank God they are few and far between. Underpaid work generally means scamping the work, and the labourer is worthy of his hire. Let working men act like men and sit and think over what I have ventured to say, and let them not be bound to any one doctor when the day of sickness comes, but let them deny themselves of all needless extravagance and join together in maintaining the birthright of every true Britain to be free and not to be a slave to any form of medical or other despotism, which I maintain many of the so-called clubs, provident dispensaries, friendly societies, are nothing more nor less.

In writing to you, I have no interests to serve except those of truth and of my beloved fellow creatures.

I am, Sir, your obedient servant,

RICHARD PARAMORE, M.D.

2, Gordon-square, London, W.C.,
January 14th, 1888.

TARDY CONVALESCENCE IN THE PUERPERAL STATE.

To the Editor of "The Provincial Medical Journal."

SIR,—I have often been surprised at the uncertainty of convalescence after parturition. I can recall three cases very vividly to my recollection within the last two years where the patients previous to their confinements were in their usual health. Two of them, the mothers of large families, had always been attended by midwives; they were in their usual health, and their labours were in every way natural; but, instead of being able to get up and be about on the 19th day, they lay prostrate, without pain, simply complaining of weakness, and unable to get up for many weeks. The third case I am attending now. She was delivered over three weeks ago of her tenth child; for a week afterwards she seemed to progress favourably, but since, has made no progress, only able to sit up in bed occasionally, and that for a very short time. Her temperature varies from 101 to 102. The lochial discharge continued about two weeks. Treatment consists of good support, of which, however, she is only able to take very little; and quinine with mineral acids as medicine. Could any of your readers recommend a different treatment for such cases, that would likely be followed by better results?

Yours truly,

J. M. G.

TO LESSEN POVERTY BY LESSENING POPULATION.

To the Editor of "The Provincial Medical Journal."

We are all anxious to possess the good things of this world, to make our existence on this planet enjoyable and happy. We are driven to this by the very intrinsic subtle force of our nature. The spirit of philanthropy impels us to share this happiness, and render it accessible to our fellow-beings (the fact of doing so constitutes the happiness of the philanthropist). Those so influenced, command the respect, and are entitled to the gratitude of mankind. These laudable intentions, this highmindedness, call for unlimited encomium, but the means sometimes adopted to attain the end in view are legitimately open to criticism. To lessen population by any other means, except by self denial, is reprehensible, physically and mentally wrong? antagonistic to every recognised code of ethics, repugnant to every fine feeling that actuates the human breast. Medical men know thoroughly well, no men better, that to thwart the vital functions, is liable to be followed by disastrous consequences. It is as well established as an axiom, that nature will not suffer with impunity. The sexual functions, when excited, require to be satisfied; gratification of this demand is peremptory, the non-compliance with this mystic process of nature and its developments, incontestably tends to interfere with the integrity of the brain. The violation of this *vis natura*, when persevered in leads, without fail, to insanity. Many an inmate of lunatic asylums may attribute his or her fall to indulgence in these proclivities. All right thinking medical men will endorse my views. All artificial means, no matter under what guise, used for preventing fecundation, or obviating this or that inconvenience, are unjustifiable. I was taken by surprise when I read the column, signed "Clericus," so much at variance with all preconceived ideas of the Scriptural fact.

I cannot realise how a properly accredited minister of religion could encourage such a depraved system, propound such a theory, and startle us with such an exposition of the text. It is universally believed (*simpliciter*) by all men of mental calibre that it was the physical act committed by Onan that was criminal. The editor has ably and exhaustively threshed out the subject in all its possible surroundings; but as a member of a profession which I respect, I add this contribution as a protest against the false philosophy which would lead those whom we are bound to direct to a state of things attended inevitably with deplorable results.

I maintain that when medical men, and others philosophically disposed, enunciate principles which are supposed to ameliorate the condition of, and raise their fellow-beings in, the social scale, they ought not to be of that class which, instead of tending to make the *honest man*, the man of noble mien, would have him go forth with nature *frustrated* stamped on his brow.—Yours truly,

W. F. FENTON, Physician and Surgeon.

Cligheen, December 17th, 1887.

MARCH 1, 1888.

[No. 75.]

Our Portrait Gallery.

GEORGE GRANVILLE BANTOCK, M.D.,
F.R.C.S. Ed.

AMONGST the gynæcological specialists of the present day Dr. Granville Bantock holds a conspicuous position, emphasized by the fact that he has but recently filled the presidential chair of the British Gynæcological Society in succession to Mr. Lawson Tait. His career affords us another instance of what may be accomplished by perseverance and hard work. It also illustrates what has been often insisted upon by so many eminent leaders of the profession, that a few years of general practice is a useful training for those who desire to devote themselves to some special branch of medicine. Dr. Bantock was born at Dunrobin, Sutherlandshire, on October 10th, 1837, and was educated at the Parish School, Golspie, from whence he went to Edinburgh University in 1854. Too young to proceed to the degree at the end of four years, he usefully employed his time by acting as assistant at Newcastle-under-Lyme and Newport (Salop) for three years, and then returned to the University for two years more, and graduated in 1861.

Selecting Chester as the first field for work, he remained there for three and a half years, seeing all kinds of practice. Ambitious, and attracted by the lights of London, he went to town in 1865, and was fortunate in being elected as Surgeon to the London Surgical Home, where he performed his first ovariectomy and first perineal operation. In 1869 he was elected Physician for out-patients at the Samaritan Free Hospital; Surgeon to the same in 1877; and full Surgeon in 1878, on the retirement of Sir Spencer Wells. In the September number of the *Provincial Medical Journal*, 1887, we published from his pen, "A Year's Work at the Samaritan Hospital," which gave a

detailed account of the operations he had performed during the year. Dr. Bantock, like most of his countrymen, is tenacious of his views, and he has had on certain occasions to fight his own. He is known to be hostile to what we know by the name of Listerism, and like all men who do not believe in popular creeds, he has had to assert his views with a certain degree of vehemence and force, conditions necessary for minorities. At the present day he can look round with some complacency, as many of his predictions with regard to the popular creed have been fulfilled. His statistics stand unchallenged, and his operations performed without Listerian precautions rival those of the school he has had to contend with.

In his presidential address, entitled "Listerism: its Past, its Present, and its Future," delivered to the Gynæcological Society of Great Britain, he defended his own practice, and showed how by the aid of pure water he could obtain as successful results as any of those who confined themselves to Listerism pure. Up to that time he had had fifty consecutive cases of ovarian and parovarian operations without a death.

Dr. Bantock is an Honorary Fellow of the American Gynæcological Society, and of the Detroit Gynæcological Society; Corresponding Fellow of the Gynæcological Society of Boston; and an Honorary Member of the Canadian Medical Association.

During the year 1887 he made a tour in the United States and Canada, giving an address on "Abdominal Surgery" to the Canadian Medical Association, and performing a number of operations, hysterectomy and ovariectomy, at Chicago, Philadelphia, and New York.

Dr. Bantock has published a number of papers and reviews in the periodical medical literature of the day, and, in the *Transactions* of the Obstetrical Society of London are to be found many contributions from his pen.

Original Communications.

ON A NEW METHOD OF TREATING SKIN DISEASES LOCALLY.

BY H. VALENTINE KNAGGS, M.R.C.S., L.R.C.P.

IV.

In considering the structure of the skin, and its mode of development in the embryo, we are forced to admit that the pulmonary, alimentary, and urinary tracts are merely covered by prolongations inwards of the skin. These lining membranes have necessarily undergone various modifications and alterations in structure to fit them for the respective functions which they are called upon to perform. The human body is, so to speak, enclosed in one vast continuous sac, the cutaneous or external portion of which is called upon to help in much of the work performed by the internal portions. Respiration, digestion, excretion, and other vital processes are thereby indirectly promoted and aided. A healthy condition of the skin is very essential to the well-being of the economy. Chronic inflammatory cutaneous diseases, apart from the nervous strain and loss of proper rest, that the itching, burning, or smarting give rise to, should be looked upon in much the same light as would be a catarrh affecting the mucous membranes of the respiratory or digestive organs, or that of the kidneys. Inflammatory diseases of the skin are now generally recognised as colds or catarrhs affecting the cutaneous structures. "Eczematous eruptions," says Dr. Mc Call Anderson, "are analogous to inflammations of the mucous membranes—they constitute, in fact, catarrh of the skin." The sooner the irritation is alleviated, and the disease itself cured, the better. I have treated in recent years a considerable number of cases of eczema solely by the local application of suitably medicated emulsions. Although I have witnessed under their use the rapid subsidence and speedy cure of chronic and long-standing eczema, I have never yet seen any bad results ensue from such a practice.

With respect to the choice of a local application, we know that some persons' skins are intolerant of greasy substances, others of lotions or watery fluids. By the use of the emulsion we effect a compromise and apply the two together in a combined form, as a single preparation. In chronic inflammatory processes connected with the skin an oozing takes place. The affected surfaces are saturated or infiltrated with a serous fluid which is frequently laden with, or contaminated by, substances inimical to healing. By the application of the emulsified ointment or lotion, the water, holding in solution the soluble ingredients of the lotion, penetrates to a greater or less degree through the cuticle and serves to diminish the inflammatory action beneath. At the same time the finely subdivided and gum-encased oil particles are left on the surface, where they promote rest and effectually exclude the air. The natural healing of a healthy wound is very similar. A supply of plasma is thrown out from which the water is gradually evaporated. The coagulated fibrin remains behind in the form of a scab or crust under which a new cuticle is formed.

In chronic cutaneous eruptions, speaking generally, the cuticle is not removed. It is preferable, therefore, in applying these remedies to rub in the application until the watery constituents have become either absorbed or evaporated and the artificial film of oil and gum alone remains on the surface.

In acute cases it is best to paint the affected part with the cream or smear it over so that it may mix with the discharge and promote the formation of a scab. Eruptions that are covered by unhealthy crusts are appropriately treated by applying the remedy thickly over them and allowing time for the watery fluids to soak into their substance.

In August, 1885, I used the permanent emulsion for the first time in a case of what Mr. Hutchinson would term eczema-lupus. This disease was of many years' standing, and had extensively implicated the right side of the face. The affected part of the skin was covered by tuberculous crusts, and an unhealthy ichorous discharge was present. Numerous ointments and lotions, and temporary mixtures of the two, were tried in vain. As a last resort a combination of a *bismuth ointment, prepared with vaseline, and a boric acid lotion was used.*

Vaseline	1 ounce	Gum	Boric acid.....	16 grains
Bismuth trisnitate, 1 dram		acacia,	Water	1 ounce
Ft. unguentum.		160 grains.	Ft. lotio.	

The patient, an elderly lady, was directed to smear this application over the crusts several times a day, and was also told not to wash it off, but to apply one layer upon another until a thick covering had been formed. Under this treatment rapid improvement took place. The discharge ceased; the scabs became less brittle, and exhibited a tendency to peel at the edges, leaving healthy skin at the margins. At the end of about three weeks from the commencement of this method of treatment the whole crust came away. The entire surface beneath it was found to be sound and healthy. With the exception of a slight amount of scaliness, and a scar of considerable extent, the patient remained free from the complaint for nearly two years. A slight return of the eruption then manifested itself, and a further use of the remedy again produced a successful result. No further return of the disease has since occurred. This case is recorded at length to serve as a typical illustration of the good effects to be derived from so simple an application, even in lupus. A few cases of an analogous character have since come under my notice, and applications similarly medicated were applied with equally satisfactory results.

In a very bad case of *lupus exedens* an emulsion basis similarly medicated was tried. The greater part of the left ala of the nose and the tissues below the left eye had become deeply involved and destroyed. At first a perceptible amount of improvement took place. The part assumed a more healthy appearance, the discharge diminished in quantity, and a remarkable, although feeble, attempt at healing evidently took place. This treatment was continued for over two months. The disease eventually elapsed into its old condition again, and no permanent good resulted from the remedy. This case proved a most instructive one to me. It is seen that even in the worst forms of lupus an evident effort to take on a healthier action may be manifested under the action of a perfectly non-irritating application.

In another severe case of *lupus exedens* occurring in a youth, an emulsion consisting of a ten per cent. salicylic acid ointment blended with a boric acid lotion had a marked effect. The tissues on the back of the hand were deeply destroyed and covered with tuberculous deposits. This patient had suffered in this way for more than nine years, and had attended as an out-patient at almost every London hospital. According to his account he had been "scraped" on several occasions. This application, and the bismuth

Yours sincerely
Geo. Grantell Barber

formula were used separately on alternate days. Under the continued use of these for a fortnight the disease began to make considerable progress. At the end of a third week, when he was seen for the last time, the eruption was almost well. Whether the improvement was permanent or not I am unable to state positively, as the patient has not been seen again.

That extended experience of this form of treatment will prove that suitably medicated permanent emulsions are remarkably curative in this disease cannot be doubted. If the salicylic acid application be alternated with another of an unirritating character the good effect of the medication is much enhanced.

In my hands emulsions have proved so satisfactory a form of skin medication that I should scarcely know how to manage without them. I have found that, with some few exceptions, the most obstinate kinds of eczema will yield under their continued use. In fact, strange as such a statement may appear to many persons, the more incurable, apparently, the disease, or the more aged the sufferer, the more quickly does the emulsion effect a permanent change for the better. Broken chilblains and the eczematous eruptions that occur on the extremities from various local causes, are especially obstinate under ordinary local remedies. A relative of mine from the "Far East" suffered much from chronic eczema affecting the toes. The complaint was contracted in the jungle. He informed me that persons so affected, and who live in tropical climates, will even make long voyages into colder and more temperate latitudes in order to get well, and then, very often, have to return incompletely cured. The application of a bismuth emulsion speedily removed all traces of this complaint in a few days in the case of my relative. A number of similar cases, all of which were of an intractable type, although contracted in England, have since been treated in the same manner. In every instance a rapid and complete cure took place in the course of a few days, or at the outside a week or two. Amongst these I may mention the case of an individual who suffered for a number of years from eczema of the fingers, due to the constant handling of irritants. The itching ceased under the treatment, and the hands were soon free from the disease, although this patient remained all the time at his occupation.

One of the principle points which attracts notice with this treatment in cases of eczema is the immediate relief of itching and irritation. This takes place almost immediately after the remedy is applied. An elderly gentleman consulted me who had been for years afflicted with chronic eczema. He had not had a proper night's rest for many months past. The pruritus was so intense that the attendant scratching made the blood flow freely. The bismuth formula was ordered to be applied when the irritation was troublesome, with further directions that no textile dressings were to be used, and that the part was to be kept as dry as possible. The patient informed me subsequently that this was the only application out of a large number that he had tried which adequately relieved the distress and enabled him to sleep. At first one application daily was found sufficient, but afterwards a single application arrested the itching for a whole week. The disease is now practically well, but he still uses the remedy at intervals of about a fortnight to make certain of thoroughly eradicating the complaint.

Another gentleman suffered similarly from severe pruritus associated with chronic eczema. Two applications of the remedy permanently arrested the itching and cured the disease.

In a third case—a gentleman suffered from severe gouty eczema—there was scarcely a part of the body that was not affected by the disease. This individual had tried numberless methods of treatment with indifferent success. The emulsion treatment speedily and permanently cured the disease. A lady friend of this patient had also suffered greatly from eczema for five years, and had tried every available remedy, she was completely cured of her ailment in a few weeks by means of the emulsion.

I give these few instances as types of many other cases in which the emulsion treatment acted with uniform certainty. The troublesome pruritus of old people is rapidly cured under its use. The irritation of chronic urticaria was effectually arrested in seven cases in which the emulsion was tried. Crude pyroligneous acid in a thin and well-diluted emulsion will be found to act well in such cases, but other formulæ are equally effective. In chronic urticaria it is generally necessary to administer internally a suitable alkali which should be continued for some time in conjunction with the local remedies, until all fresh wheals and papules have ceased to make their appearance. In the eczema capitis or scald head that occurs in infants during dentition, the medication of the emulsion, in recent acute cases requires to be varied to suit each case individually. The bismuth formula certainly proves rapidly curative in chronic cases and especially in those that have resisted other forms of treatment. Where this formula has failed I have employed oxide of zinc with glycerine or salicylic acid as medicaments with good results. According to my experience the acute eczema of infancy is the only form of catarrhal eruption which does to any extent resist the action of these preparations. Why they should rapidly cure one case of this disease in an infant and fail to benefit another of an apparently similar character is one of those problems which at the present time I am certainly unable to solve satisfactorily.

Permanent emulsions have proved very effectual in many cases of psoriasis. This basis when suitably medicated is the best I have ever used in this complaint. After a variable time the application dries; effectually covers up the affected part; and curative drugs are retained in continual contact with the hypertrophied papillæ. Chrysarobin, trisnitrate of bismuth, or salicylic acid, if used as medicaments in quantities of from five to ten per cent. upwards, can be applied in this manner. The chrysarobin emulsion is a cleanly compound. It should be gently rubbed in for several minutes. Owing to its drying on as a film it prevents staining of linen or surrounding parts. One of the most satisfactory formulæ to use in psoriasis is constituted as follows:—

Paraffin molle	$\frac{1}{2}$ oz.	Gum	Boric acid ...	8 grains.
Zinc oxide	1 dram	acacia,	Glycerine ...	1 dram.
Pure liq. carbolic acid, M. i.		80 grains.	Aqua	$\frac{1}{2}$ to 1 oz.
Ft. unguentum.			Ft. lotio.	

Place the ointment in a warmed mortar. Incorporate with it the gum. Then add two drachms of hot water and finally the remainder of the water mixed with the ingredients of the lotion.

I may add, by the way, that the action of these remedies on domestic animals suffering from various eruptions is little short of magical. I have suggested this plan of treatment in several cases of the kind. The eczema so common to cats and dogs is generally removed by a few applications of the bismuth formula. Parasitic eruptions also can be cured with equal rapidity by an emulsion medicated with sulphur.

In conclusion, I would remark that if anyone is sceptical

as to the remarkable results to be obtained by this method of treating skin diseases, it is easy to put the matter to the test in some obstinate case of eczema. He will in all probability not have to look far to find one, for this complaint is prevalent enough in all conscience. If after that, he is still unconvinced, I am afraid he is beyond the reach of any argument of mine.

FROM GENERATION TO GENERATION: A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.
F.R.S.L., ETC.

(Continued from page 63.)

Diseases of the Kidneys, etc.—That a predisposition to diseases of the kidneys, bladder, and generative organs, is hereditarily transmitted, and characterises certain families for generations, is a fact which cannot be denied; and if my arguments as to the influence of heredity in the diseases of the circulatory, nervous, and respiratory systems are of any avail, we shall have no difficulty in understanding why this is and must be so. For the human body being subject to the law of heredity in its every organ and tissue, it assuredly follows that what is true physiologically and psychologically, must, as a natural sequence, be true also pathologically. We are prone to talk of the constitution of an individual. What do we mean by the term, and what does it involve? A sound constitution has been defined as the harmonious development and maintenance of the tissues and organs of which the body is made up. Whence does it originate? From the union of a healthy sperm and germ cell in the maternal womb. To this same union I have already traced the source of heredity: so that every constitution has its foundation laid, and its deficiencies and potentialities developed and maintained in accordance with the law of heredity, to which they are alike subject from the time a germinal vesicle is produced by the fusion of the germ with the sperm cell. Irrespective of the *definite inherited forms of disease* which contribute to constitutional unsoundness, the latter condition may also be the result of defective or *deficient vitality*, which may be general or local. When general, this deficient vitality is frequently observed in "the children of parents one or both of whom are in advanced life, or whose vitality on one side or the other has been reduced by excesses, such as alcoholic or venereal. Exhausted vitality from prolonged disease, *e.g.*, phthisis or tertiary syphilis, affecting either parent, may determine the death of the offspring at an early period from mere failure of nutrition, or may cause it to succumb to acute disease not necessarily associated with any inherited tendency of a special kind." Deficient vitality may also be local, *i.e.*, affecting only certain tissues and organs, or involving certain systems, as the nervous, the respiratory, the vascular, generative, or digestive; and amongst those diseases which are the most assuredly and markedly hereditary, none are more so than those of a degenerative form, including structural heart diseases, atheromatous vessels, emphysema, certain diseases of kidney, etc. All these partake of the nature of premature senility of organ or tissue, consequent upon some inherent deficiency in their vitality. "Although the constitution of an individual begins with his life, it is nevertheless the resultant of the constitutional peculiarities of many antecedents. This being so, tendencies to disease may date far back in the pedigree, to be called forth from time to time by favouring circumstances." What we have practi-

cally to remember is, that in addition to such definite inherited forms of disease as congenital syphilis, gout, scrofula, tuberculosis, cancer, asthma, and several neuroses, the relative soundness or unsoundness of individual constitutions is also dependent upon a local or general defectiveness of vitality, which is hereditary, and which will tend to develop disease in the impaired organ or tissue. Constitutions are liable to be rendered unsound, not only by definite inherited forms of disease and defective vitality, but by the wear and tear of life in its environment. Here again we have the constitutional vigour so impaired, subsequently to birth, by pernicious surroundings, that constitutional diseases are thus engendered, and passed down as a legacy to be inherited in future generations, in the form of scrofula, rickets, phthisis, etc.¹

We thus see that there is no organ or tissue of the human body which is not subject to heredity in disease as in health: the fact being that, in one as in the other, like begets a predisposition to like, capable of being modified by variability, or even neutralised by marriage into a new stock, for a generation, but never lost. A predisposition to degenerative diseases of the kidney is therefore as much a fact as that scrofula or phthisis are the results of the development of a pre-existing disposition in the organs or tissues affected by them. The three degenerative diseases of the kidney known under the generic name of Bright's disease will afford an example. The first, or inflammatory form, may be acute or chronic, and usually affects the tubules; the second, or waxy, lardaceous, amyloid or albuminoid is degenerative, and originates usually in the vessels; whilst the third, the gouty or cirrhotic form, is also degenerative, and originates in the fibrous stroma. What has heredity to do with these conditions? Let us seek our reply in the etiological sources of each of these affections. The inflammatory affection is said to be caused by exposure to cold, and by scarlatinal and other blood-poisons: the latter I shall consider presently, when I come to deal with heredity as affecting the acute infectious diseases. With regard to exposure to cold, we have already seen that the catarrhal diathesis is universal, but may be, and is, differently distributed in different individuals. Let us suppose, for example, that a parent has in early life suffered from this inflammatory affection of the kidneys, however caused: however competent to discharge their functions afterwards, the kidneys during his life will bear the brand of what they have suffered—they will be *somehow* different from what they were originally. This parent has a child or children who have, in common with humanity, inherited the catarrhal diathesis, subject in his or their cases to the combined catarrhal predisposition of both father and mother. From what we have already seen of the action of heredity, is it too much to assume that one of the father's children will inherit a predisposition to the pathological taint in his father's kidneys, and on exposure to a similar cause will almost inevitably suffer from a similar affection? I trow not; but, unfortunately, I have no cases at my disposal to bear out my argument. At any rate, it is easy enough to adduce cases of like heredity in reference to other organs and tissues, and if so in these, why should the kidneys be excepted? I firmly believe that as every vestige of the human body is subject to heredity physiologically and psychologically, so it must be, and is, with regard to its pathology: for disease is but impaired function or degenerative change; and if, in health, every

¹ Dr. Douglas Powell.

cell, membrane, muscle, bone, and viscus—every element of man in his dynamism—is subject to the law of heredity, by a parity of reasoning, I cannot see why, if certain morbid conditions are universally recognised as hereditary, a predisposition to every morbid condition may not be traced to the same influence.

The waxy or amyloid disease of the kidneys is said to be caused by phthisis, syphilis, caries, profuse suppuration, and other exhausting conditions, and is often associated with waxy degeneration of other organs, especially the liver, spleen, and intestinal canal: in fact, it might be defined generally as a constitutional condition dependent upon the scrofulous diathesis. As in the foregoing, and for similar reasons, this condition is capable of being transmitted hereditarily, at least, so far as a predisposition to its development is concerned. The gouty or cirrhotic form of Bright's disease depends for its causation upon alcoholic intemperance, the poisons of gout and lead, and other conditions which are unknown. In the course of its development, hypertrophy of the heart, with sclerosis and degeneration of the vessels are frequently associated with it, inasmuch that Sir William Gull and Dr. Sutton regard the affection as only symptomatic of a constitutional condition characterised by hypertrophy of the walls of the small arteries, due to a fibroid growth in the external coat of the vessels. Dr. George Johnson, on the other hand, regards the hypertrophy as "a consequence of the obstruction which impure blood invariably meets with in the capillaries." Whichever view may be correct, I have certainly seen cases in which the cirrhotic form of kidney disease was associated with cirrhosis of the liver, sclerosis of the blood-vessels, mitral stenosis, and, curiously enough, with sclerosis of the posterior columns of spinal cord. There is, at least, much in favour of the belief that the so-called "gouty kidney" co-exists with a constitutional condition, however imperfectly understood, and that like all other constitutional conditions, it is capable of being transmitted, as a predisposition, hereditarily. I have chosen the three forms of Bright's disease as illustrative of my argument because in themselves they constitute the most important of the diseases of the kidney; but I might readily have included syphilitic, malignant, and tubercular disease, suppurative inflammation, acute and chronic atrophy, cystic, hydatid, and fatty disease, pyelitis, etc. Those to which I have referred are, however, I trust, sufficient to show that as in every other organ and tissue of the human body, the kidneys are similarly predisposed to disease, and that this predisposition is hereditarily transmissible.

Renal and vesical calculus—similar morbid conditions—are undoubtedly hereditary. I could adduce many striking instances of this fact, but the following will suffice:—The first case is mentioned by F. Hoffmann. The Lady of the Prince Moritz of Zeitz was afflicted with nephritis; she was delivered of a daughter, who, from the moment of her birth, suffered very great pains, especially when passing water. The child lived only three weeks. At the *post-mortem* examination there was found in the bladder a stone as large as the stone of a peach (*instar mali Persici*). Gaubius, as alluded to by Steinau, assisted at a lithotomy performed on a boy of ten years of age, whose father had twenty-five years before undergone the same operation. The father, upon seeing the stone taken from his son, assured them that it was quite like that taken from himself. Gaubius compared them; and found they were indeed like each other in every respect, except in size, the father's being somewhat larger than that of his son. There is also

the well-known case of the Perigordian philosopher, dear quaint old Montaigne, who suffered severely from stone in the bladder, which he had inherited from his father. Stahl also assures us that he never saw a person suffer from lithiasis, whose father or some other near relation had not been afflicted with this same complaint, or with gout.¹

The different maladies peculiar to women, according to the opinion of the most skilful observers, frequently occur hereditarily, or are transmitted as a predisposition to the same. Nothing is of more frequent occurrence, says Stahl, than to see all the different irregularities of the menses, pregnancy, puerperium, the milk, etc., that had taken place in the mother, appearing also in the daughter; and every observant physician must have frequently noticed this fact. The relative susceptibility of individuals to the syphilitic and gonorrhœal virus—to stricture, catarrhus vesicæ, enlarged prostate—all of which involve a hereditary element, might be here noticed, but I shall allude to some of these affections hereafter. I therefore, maintain, that in all diseases of the kidney and genito-urinary tract there is a pre-existing heritable disposition of tissue and organ, whether of late or early descent, and that this view is well supported by facts in every day practice, if they are only recognised and appreciated aright.

Diseases of the Chylo-poietic System.—The mere enumeration of these diseases would monopolise almost all the space at my disposal for their consideration. I shall, therefore, content myself with some brief general remarks as to how they are affected by heredity. If there is any truth in my previous statements regarding the diseases already considered, and if my arguments have anything to recommend them, it follows, by analogy—if I have established as a fact that pathological processes are subject to heredity because the physiological and psychological nature of man is undoubtedly inherited, although subject to individual modifications—that what is true of one system must be true of all, and that as every tissue and organ in the human body bears the brand of heredity in the discharge of their every function in health, so must they also in disease, which I regard as functional derangement or degenerative change in tissues or organs which have been inherited. Again I must guard myself from being misunderstood. I do not mean that the diseases of ancestors or parents must inevitably be transmitted to their children (although such cases occur, perhaps, more frequently than we wot of); but what I contend for is that the physiological and psychological natures of ancestors and parents being handed down to their children, with certain individual modifications, it must follow that the brands of disease upon, or the taints of disease within their tissues or organs, must be likewise transmitted as predispositions to the same. When considering the physiological and psychological aspects of heredity, in this series of papers, I think I proved without a doubt that there was no element of man either in his organism or in his dynamism that was not subject to the law of heredity; and if this is so it seems to me but a natural consequence that with his organic or dynamical peculiarities he should also transmit a predisposition to the weakness or deficiency of his tissues or organs produced by disease in himself, to become re-developed in his children under circumstances favourable for such development.

With regard, however, to the diseases of the stomach and intestines, of the pharynx and œsophagus, of the

¹ Dr. Steinau.

peritoneum, of the spleen and pancreas, if heredity and variability necessitate the fact that these organs differ from each other not only organically, but functionally in the cases of different individuals, and that in no two individuals are they precisely the same either in their organic potentialities or functional peculiarities, it assuredly follows that they are differently predisposed to organic and functional derangements and diseases, and it is only fair to assume that heredity and variability are also responsible for this fact. It is at least safe to affirm that all the diathetic diseases—tubercle, scrofula, cancer, syphilis, gout, *et hoc genus omne*—are markedly hereditary, and that every organ and tissue of the chylo-poietic viscera are subject to each and all of these diseases admits of no doubt. Of other morbid conditions of the chylo-poietic system which are frequently inherited I may mention helminthiasis, hæmorrhoids, dyspepsia, hernia, fœtor oris, and dropsy; to these might be added many kindred conditions, but those mentioned will suffice. With regard to helminthiasis it is a fact, as proved by daily experience, that the children of parents who are infected by intestinal worms (especially *ascaris vermicularis* and *ascaris lumbricoides*) are also attacked with these parasites, often at a very tender age, when they cannot have been caused by any noxious influences; and sometimes even from their very birth. Dr. Steinau says he had frequent opportunities in the Hospital for Diseased Children, in Berlin, to assure himself of the hereditary character of this complaint. The hereditariness of hæmorrhoids is of too frequent occurrence to render it necessary to enlarge upon it. Who has not witnessed dyspepsia, in its protean forms, handed down from parent to child, and been struck by the frequency a patient will say "My father (or mother) had a very weak stomach too?" Hernia has been known to have been inherited through many generations. Many competent writers, says Steinau, have cited cases to prove this; and Richter saw several children, whose fathers were ruptured, suffering from the same complaint, having in each case arisen without any external cause, and quite spontaneously. Speaking of dropsy, Rougemont, supported by the testimony of several credible writers, says that it is proved by numerous observations that the children of such parents as have died of dropsy became at a certain age also dropsical. Many cases have been noticed of dropsical women being delivered of dropsical children—particularly one case quoted by Hufeland, and observed by Olivier. Chronic fœtor oris, which does not appear to be produced by any visible local cause, is also often hereditary.¹ To these might be added abdominal cramp, flatulence, constipation, pyrosis, and many other allied conditions.

Regarding the diseases of the chylo-poietic system as a whole there is scarcely one of them to which heredity cannot be said to have predisposed. Of course the influences of life and circumstances have to be estimated in every case as factors in the production or development of disease; but I maintain that in almost every case there is a pre-existing disposition which has been inherited, and which acts as the source from which morbid processes spring, or as the foundation on which they are laid. To quote an illustration already given, why should several individuals exposed to the same noxious influence—say a chill—be so differently affected? One will have as a consequence an attack of influenza or bronchial catarrh, another sore-throat, another rheumatism, another bronchitis or pneumonia, another lumbago, and so on. Why are

some individuals so prone to attacks of erysipelas, biliousness, sick-headache, etc.? Because they differ from each other as individuals in power of resistance; because of pathological habit; but principally because of constitutional predisposition which, in nine cases out of ten, will be found to rest upon a basis of heredity. Their fathers or mothers may be found free from any such affection as the children respectively suffer from; but this is not enough to prove their non-hereditary origin. We must enlarge the cycle of heredity and inquire further back in the pedigree, and if this inquiry also gives a negative reply we must remember that hereditary diseases are somehow mysteriously related to each other, and may in many instances be found vicarious; thus it is possible that the father may suffer from hæmorrhoids, and the son from dropsy; or the first from gout and the latter from stone; but still in these cases the dropsy as well as the stone must be considered as hereditary.

Try as we may, there is no such thing as getting rid of heredity, for it is the inexorable law of our being. No force in Nature can be lost; and as whatever we *have* or *are* we owe to heredity, save the action of our environment, we must bow to the inevitable, and admit that as our physiological and psychological being is subject to the action and inter-action of this great law within us, so also we are more or less predisposed to the morbid processes which assail us during our lives, and that these predispositions we shall pass down to our children, however ignorant we may be of the fact, or however we fail to recognise or appreciate it. As the past slumbers in each one of us, so do the potentialities of the future—the welfare and commonwealth of our race!

(To be continued.)

OCCLUSION OF COMMON GALL DUCT, AND DIFFICULTIES IN DIAGNOSING CAUSE OF OBSTRUCTION.

By ANDREW SCOTT MYRTLE, M.D.

(Continued from page 52.)

CASE 7.—Mr. R—, æt. sixty-two, gentleman farmer, came to me with a letter from his ordinary adviser. History: "For years the patient has been suffering from dyspepsia of the most severe and varied character, the pain and sickness after eating solid food being so marked as to cause one to suspect ulcer of the stomach. These symptoms would gradually subside, to be replaced by the most violent frontal headache, which lasted from twenty-four to forty-eight hours, and this again was followed by bilious vomiting, accompanied with severe spasm of gall duct, followed by jaundice. Latterly he has been losing weight, has become very much depressed and enfeebled, and as he has not responded to any of the remedies prescribed, I have advised him to pay Harrogate a visit, and see what its waters can do for him under your advice." Ulceration of stomach, cancer of pylorus, cancer of liver, and gall stones had all in turns been supposed as the possible condition of this patient. After his arrival, for three days he improved in every respect—appetite, strength, and sleep—but at the end of the third day he fairly broke down; spasm of gall duct, vomiting, prostration, could retain neither food nor medicine; matter vomited passed from light yellow to coffee brown, and then became quite black; stools ditto. On examination I found the liver two and a half inches below ribs and left lobe especially full and tender on pressure; pulse 120; temperature 102°3°;

¹ Steinau.

complained of intense thirst and intolerable heat. I applied hot poultices to liver and stomach, abstinence from all food, giving nothing but ice; $\frac{1}{4}$ -grain morph., $\frac{1}{60}$ -grain atropia hypodermically. This put a stop to both pain and vomiting. I then ordered $\frac{1}{4}$ -grain morph. with $\frac{1}{2}$ -grain hyd. iod. vir. every four hours. His condition looked extremely grave, and I fed him on Brand's essence of chicken-peptonised, with iced champagne; hot water bags were kept over liver constantly. At my evening visit I thought he would be dead before morning; to my surprise he was better, and of his own accord had asked for and drank two half-pint glasses of hot sulphur-water. This had acted freely, bringing away a quantity of glutinous pitchy looking matter. I stopped the hyd. vir. All day he at intervals of from two to three hours passed the same kind of motions, to the relief of all his symptoms. He began to ask for strawberries and cream, and for two or three days he took little else. After that I put him on No. 2 Koumiss; this he enjoyed and drank freely of. Each morning he had his purge of sulphur water, and he gradually got well, or rather, I should say, resumed his usual condition as a dyspeptic. The grave symptoms in this case arose from long-standing biliary retention, involving chemical changes in the pent-up secretion, acting as a poison; at all events that is my solution of this singular case.

CASE 8.—Mrs. D—, æt. forty-four, dark complexion, went to Brighton to reside some two years before I saw her. All the time she remained there she never felt well, her appetite failed her, or was capricious, she felt feverish, out of sorts, and depressed, had steadily lost weight, was often so drowsy she could scarcely keep awake during the day, and at night she was fidgety and restless. Here I may remark that I have frequently observed the same symptoms develop in people of Mrs. D—'s temperament whenever they visit the seaside. Tongue foul, breath most offensive, sickness constant, skin jaundiced, slight hæmorrhage from nose, gums, and lower bowel; liver enlarged and tender; has had three attacks of jaundice, preceded by great pain above umbilicus. Was treated for gall-stones; none ever discovered. The symptoms were so like those of former case I jumped to the conclusion that it was identical. Put her on mercury (calomel) with a little opium for two days. On the morning of the third I ordered the sulphur water, warm, in full doses, and the result was a copious discharge for days (seven I think) of the same dark sticky pitch-like stuff. Here I had little difficulty to contend with; all the symptoms which had so long troubled her gradually disappeared, and the liver resumed its normal condition.

CASE 9.—Mrs. A—, æt. fifty-two, had for above twelve months been in failing health; during that time she had been more or less confined to bed, on account of the impossibility of her wearing ordinary clothes, as anything the least tight round the waist caused pain and sickness. The liver was easily mapped out, and its lower margin was three and a half inches below the ribs, the surface felt nodulated, or more correctly speaking, uneven; there had been frequent but slight bleedings from the nose and gums. She had been jaundiced several times but to no great extent; her mucous membrane had been more or less irritable, and there had been constant nausea, pain under right shoulder, and great acidity; she looked cachectic as well as anæmic; no fever, tongue flabby, irritable, white fur at back, urine loaded with uric acid crystals, stools light coloured and offensive. She was supposed to be suffering from malignant disease and occlusion of gall

duct. I confess I took the same view, and for weeks absolutely refrained from treatment. The patient at the end of two months was, I thought, rather better than worse, and the liver had certainly diminished perceptibly in bulk, and the nodules were on careful examination no longer felt. Then I determined to adopt a more active course, and prescribed at night pil. Plummer with Carlsbad salts following morning. At the end of a fortnight there were decided signs of improvement, bile appearing in fair quantity in the motions, less acidity and tenderness. Continued same treatment for a fortnight longer, when I put her on full doses of quinine, with the best results, convalescence. I had the satisfaction of telling her family that I had, at first, been completely at fault in my diagnosis, and that, instead of suffering from cancer, she had been the subject of chronic congestion. I should add that for weeks I employed a liver pad, saturated with nitro-hydrochloric acid lotion, almost constantly, and that I dieted the patient most strictly, allowing only the simplest forms of nourishment, and no stimulants whatever. This patient could not bear the smell of sulphur water.

CASE 10.—Mrs. G—, æt. seventy-five, began to complain of nausea and bitter taste in mouth, in September, 1886; this continued till October, when she was attacked with violent hepatic colic, great tenderness of right hypochondrium, anorexia, jaundice; urine full of bile, stools quite white. Notwithstanding all these grave symptoms the old lady would go about, attend to her domestic duties, and do just as she liked. The usual remedies were had recourse to, without any result. Every ten or twelve days she had a renewal of colic, pain in the liver, and increase of jaundice. This went on till end of January, 1887, without much loss of flesh, although she had to live almost entirely on milk and farinaceous foods. All this time the excreta were carefully examined, the stools never contained any concretion, and never showed a trace of biliary pigment; she was so stout that I could not ascertain the physical condition of the liver, and was utterly at sea as to the etiology of the case. I had given every medicine I could think of, tried every mineral water in turn, and at the end of the fourth month the patient was the same as when I first saw her. One thing I had not tried was bed, so there I put her and kept her, having no hope of recovery; the room was kept at the temperature of 60° Fah.; one of the most painful symptoms in this case was flatulence, and for this I prescribed a pill, with pepsin porci, manganesii sulph., each 2 grs.; ext. nuc. vom., gr. $\frac{1}{4}$, one thrice a day; in about six weeks the motions began to show some bile; this gradually increased, the skin and urine cleared, and about the middle of April the patient was perfectly well, and going out daily; this was evidently a case of chronic catarrh, and considering the age and obstinacy of the subject, a very singular one too. She maintained that the pills cured her, I that it was the uniform temperature and bed.

CASE 11.—Mr. S—, æt. sixty, when perfectly well in July, 1886, was caught in a thunder shower, drenched to the skin, and remained for two hours in his wet clothes. Next day got up, feeling well, ate usual breakfast; two hours after was seized with intense pain in gall duct, then followed cramp of stomach, which was only relieved by an emetic of mustard and hot water. In twelve hours jaundice—the liver becoming gradually more and more congested and painful, with high fever, intense thirst, and great prostration; calomel and opium, with ipec., were given; hot stupes over liver;

the motions became as white as milk, gallstones were suspected and carefully looked for, but none found, as the liver was distinctly felt considerably enlarged and tender, smart purging was enforced, with the greatest benefit, and in a week Mr. S. was doing work. Four weeks after first attack he had a second, clearly brought on by his having, whilst hungry and exhausted, partaken of unwholesome food, all the symptoms returned exactly in the same order, but with increased force; two doses of calomel of three grains gave rise to foetor, spongy gums and slight salivation; purging again was had recourse to, and the more he was purged the stronger and better he felt; for a week the stools remained quite white, the urine like porter, then gradually things came right. I have brought this case as a contrast to the preceding one, it being as good an example of acute catarrh as the other was of chronic.

I might multiply cases easily, but shall end this paper by one or two practical remarks on certain premonitory signs of liver disorder. First, I have observed an almost constant metallic taste, and that with this coppery taste, they have very commonly noticed that their linen was dyed orange colour by their urine. Second, that a common sensation was an unnatural craving for food, when there should have been no such desire shortly after a meal, this was so intense it amounted to gnawing, and must be satisfied. Third, everyone knows how the temper is affected by the state of the liver, but the mental faculty, which is most inconvenienced is the memory, as regards matters, important and trivial. The last symptom I shall name is a sense of weariness and weakness in the muscles of the lower extremities, they feel quite unequal to the most moderate work, and after it, ache as if they had been over-strained the day before. As regards treatment I pin my faith to mercurials, saline purgatives, diet and warmth. Of all purgatives I prefer natural mineral waters, and whilst admitting the power and value of many of the foreign springs, after much experience of their use, I can, with perfect good faith, affirm that the strong sulphurous springs and baths of Harrogate are administered in the great majority of functional disorders of the liver and digestive organs, with quite as much success and lasting benefit as are those of any country.

THE GENERAL PRACTICAL USES OF ELECTRICITY IN MEDICINE AND SURGERY.

By W. E. STEAVENSON, M.D. (CANTAB.), M.R.C.P.,

IN CHARGE OF THE ELECTRICAL DEPARTMENT (LATE CASUALTY PHYSICIAN TO), ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO THE GROSVENOR HOSPITAL FOR WOMEN AND CHILDREN.

(Continued from page 57.)

Electrolysis.—The power which electricity possesses of splitting up all chemical compounds into their constituent elements, is destined to play a most important part in the practice of surgery. There is no destructive agent employed by the surgeon at the same time so potent and so entirely under his control. It can be applied to narrow passages of the body, and to other parts difficult of access, in a way and in cases that it would be impossible to apply any other agent. It is a more effectual and elegant means of applying caustic than any other we possess. It can be most accurately localized at the part it is wished to affect. The amount used, and the extent of tissue to be destroyed, can be regulated to a nicety; and its action can be commenced and arrested at any moment at the will of the operator. The

general practical uses of electrolysis are so important and numerous that the subject deserves separate treatment. I hope in a subsequent paper to explain the theory of, and give the details of the mode of carrying out, electrolysis, in some of the affections in which it is most useful. Among others it is used in the treatment of aneurysm, nævi, the removal of superfluous hair from the face, in-growing eyelashes, hairy moles and warts, port-wine marks, scars, strictures of all sorts—in the urethra, rectum, or œsophagus; obstructed lachrymal ducts and the Eustachian tube, stenosis of the os uteri, and many of the other diseases of women, as dysmenorrhœa and fibroid tumours, and in most of them it is more effectual than any means hitherto adopted.

Galvano-Cautery.—This is another mode of employing electricity, which is different from any of those I have already mentioned. In galvano-cautery we use the power which electricity possesses of heating metal, so that it can be used as an actual cautery, but in ways in which no other form of actual cautery can be used. The battery, also, which is required for this purpose, is different to the batteries used for galvanism, Faradism, or electrolysis. In the galvano-cautery battery there are usually only two, four, or six cells, but the surface of the elements are as large, and placed as closely together, without touching, as it is possible to make them. This is done for the purpose of reducing the internal resistance. Outside the battery the circuit is completed through the metal part of the instrument it is wished to heat. At this point the current meets with a comparatively high resistance, and the metal is heated to the required intensity. If the current is used too strong the metal may be fused.

The galvanic has several advantages over other forms of cautery. The instrument to be used can be introduced into the cavity of an organ, or along a passage leading to a diseased part, before it is made hot; if a wire loop is to be used it can be adjusted round a growth or other structure to be removed, deliberately and carefully, before the circuit is closed. The heat can be regulated and its action commenced and arrested at the will of the operator. These details are under his control more thoroughly and completely than with any other form of cautery known to surgery. If the cauter is kept at a dull, red heat, it acts as a styptic, and no bleeding need accompany an operation performed by its means; and there is a singular freedom from pain after the use of the galvano-cautery as compared to cases in which the knife or an ordinary *écraseur* are used. The process is antiseptic, and the eschar which covers the wound protects it and renders it less liable to purulent infection.

The disadvantages of the galvano-cautery are that the batteries and apparatus are expensive, and require frequent attention; an assistant possessed of special knowledge and skill is almost a necessity; whereas with the actual cautery or Paquelin's thermo-cautery the help of any intelligent individual is sufficient. When electrolysis can be used instead of the galvano-cautery, the objectional smell of burnt animal tissue can be avoided, which is inseparably connected with the use of the latter. I may here take the opportunity for pointing out that electrolysis and galvano-cautery are two entirely different things, and require entirely different batteries and apparatus. Electrolysis destroys by direct chemical decomposition, and there is no actual burning; galvano-cautery destroys by actual heat. It is very common for these two applications of electricity to be confounded together, and spoken of as acting in the same way. Galvano-cautery is most useful in removing pendulous growths such

as pedunculated tumours, polypi, and piles; in the removal of the tongue, penis and cervix uteri, and in other affections, especially those of the female genital organs.¹

The Electric Bath.—Both the continuous and interrupted current are used in treatment in the form of an electric bath. The bath should be composed of some non-conducting substance, such as porcelain or wood. In giving a general electric bath, that is intended to influence the whole system, a large copper plate is placed at the head and another at the foot, and these plates are connected respectively to either pole of the battery. The bath is filled with water, about the temperature of 104° Fahr., to such a depth as to rise above the top of the plates. The patient's feet may be placed against the plate at the foot of the bath, but the neck and shoulders should be protected from the other plate by a wooden frame, across which is stretched broad pieces of webbing. When it is required to apply the current locally, as through both hips, smaller copper plates are used, and one placed on each side of the bath at a level with the hips. For the galvanic current a bath made of copper is sometimes used. The bath itself is then connected with one pole of the battery, and a movable electrode, attached to the other pole, is applied to the part of the patient it is wished to treat. The human body immersed in water is a better conductor of electricity than the water itself, and the current passes through that part of the body which is directly between the two poles. If salt or an acid is added to the water, then the water becomes the better conductor, and the current will pass through it entirely, and avoid the patient. General galvanic and Faradic baths are used in constitutional states of the system, such as debility after long illness, or when produced by any other cause. The Faradic bath is usually in these states found the most useful. The galvanic bath is particularly useful in chronic rheumatic arthritis, in gonorrhoeal rheumatism, and in general lead poisoning. We have also found it of great service in the treatment of lateral sclerosis. In chronic rheumatic arthritis its beneficial effects can be greatly increased by a judicious employment of massage after each bath. Several patients with general rheumatoid arthritis have been treated by the author with marked improvement. The thickening around the small joints has decreased, and the patients enabled to walk and use their hands in a much better way than before the treatment commenced. They have not been thoroughly cured, but have been benefited to a greater degree than by any other form of treatment. When one joint such as the hip or shoulder has been chronically affected with rheumatism, its treatment by the galvanic bath, followed by passive movement, offers the best chance of relief. The baths may be given every other day, and should last from ten to twenty minutes.

Electro-magnets.—Electro-magnets are used for removing pieces of steel from the eye. The magnet consists of a pointed piece of soft iron or steel, around which is a coil of wire. A current from one or two galvanic cells is allowed to pass through the coil, and during its passage the piece of pointed steel becomes a magnet. The strength of the magnet depends upon the length of wire which is used to form the coil. Very strong magnets are produced in this way, and have also been found useful in removing needles and pieces of steel or iron from other parts of the body as well as from the eye. The presence of a needle or piece of

steel in the tissues can often be determined by the use of another needle that has been magnetised. The magnetised needle is suspended from its middle by a piece of cotton and moved slowly over the suspected part, and when it is brought near to the hidden piece of metal it dips, and will often indicate very accurately the position of the object that is being sought for. It can then be cut down upon, and if not too tightly fixed can be removed by the electro-magnet or by forceps. If the embedded needle or piece of steel is fixed too tightly to be removed in this way, a very ingenious device has been described by Mr. Littlewood.¹ The offending piece of metal is connected with the negative pole of a galvanic battery, an electrode connected with the positive pole is placed on some other part of the body, and a strong current allowed to flow for some minutes; electrolysis takes place around the fixed needle, and in a short time it becomes so loosened that it can be easily removed. To detect the presence of a bullet an electric probe has been used. The probe consists of two parallel rods of metal insulated from each other up to their tips. Included in the circuit is an electric bell. When the probe touches any hidden pieces of metal in such a way that the ends of both the insulated rods rest upon it, the circuit is completed and the bell rings. This probe has often been found useful in military surgery.

Electric Light.—Great advances have lately been made in the employment of electricity for the purpose of lighting up the cavities of the human body, and for facilitating operations in these cavities. No other form of light can be held at all times in such a position as to prevent it casting a shadow, or in fact upside down. A small electric light can be held in the mouth during the operation for cleft palate. It can be introduced into the rectum or vagina when held open by a speculum; and if necessary the interior of the uterus, after dilatation of the os, can be lighted up, and by this means the internal surface examined. The heat evolved is very trifling, and not sufficient to cause inconvenience. The lamp is mounted on a handle possessed of binding screws, by which it can be attached to a battery; and concealed in the handle is a rheostat, by which the intensity of the light can be regulated by a sliding button. By means of the button the circuit can also be made and broken, and thus the lamp rendered incandescent or extinguished. For examining the larynx, a mirror can be fixed so as to project over the end of the lamp, by which the rays can be reflected to the vocal cords. Means have also been devised for attaching small electric lamps to aural, nasal, or vaginal specula. In the *British Medical Journal* for December 3rd, 1887, p. 1211, a case is recorded in which the author assisted Mr. R. W. Parker in the removal of a tumour from the female bladder by galvano-cautery, the bladder being illuminated by the electric light. A supra-pubic opening was made into the bladder, through which the light could be introduced, and by its means the interior of the bladder was thoroughly lighted up; the position and attachment of the tumour was plainly seen, and the wire from the galvanic écraseur, which was introduced through the urethra, was accurately adjusted around the base of the tumour before it was made hot. The removal of the tumour was effected without the loss of a drop of blood, and the seared scar on the floor of the bladder could be well seen and examined; and several suspicious-looking points were again burnt with the galvano-cautery. The girl made a complete recovery. Recently a new electric cystoscope has been introduced from

¹ Vide "Handbook of Gynæcological Operations," by Alban G. Doran. J. and A. Churchill, 1887, Chapt. v.

¹ *Lancet*, Aug. 27, 1887.

Vienna, by which the male bladder can be effectively illuminated. A description of the instrument is to be found in the *British Medical Journal* for February 4th, p. 240. An independent battery, composed of a few large cells, is required for the use of any of these small electric lamps; and it is necessary, for the purpose of regulating the light, either to have a rheostat connected with the battery, or in some way inserted into the handle which carries the lamp.

Space does not permit me to dwell upon several minor uses to which electricity has been put as a handmaid to medicine and surgery; but from what has already been written it might appear that nearly every complaint can be cured or treated by this agent. Such is not the case. It will be found that certain complaints can only be relieved or cured by certain forms of electricity or the application of electricity in certain ways, and that if employed in other ways or in other forms, it only does not cure the affections for which it is used, but in some instances makes them worse. This brings me to another subject.

The danger of the Indiscriminate Use of Electricity in the Treatment of Disease.—For any benefit to be derived from the use of electricity, it must be used intelligently and appropriately for the affection for which it is prescribed. Duchenne was the first to point out, that to obtain any good results it must be applied locally, *i.e.* to the part it is required to influence. The tendency of all electrical currents is to take the shortest route possible to complete the circuit, always, of course, choosing the road that offers the least resistance. In the treatment of incontinence of urine, if one electrode be placed on the lower dorsal spine and the other above the pubes, the sphincter vesicæ is almost completely without the circuit, and receives very little direct influence. I have known electricity so applied in the case of females from feelings of delicacy, when the sphincter was, no doubt, at fault. If the current is not applied directly to the part affected, it is best to dispense with the use of electricity altogether. To produce an effect upon an organ, the more the current is localised the greater is the influence exerted. A weak and therefore often painless current can be used if applied locally, but if not so applied a much stronger current would be required to produce the same effect, and one perhaps not able to be borne without an anæsthetic. Many of the good results of electricity have been unattained and entirely disbelieved in because the current has been passed through the body in a haphazard way, often with the patient only holding the handles of some kind of electrical machine, which has produced most uncomfortable sensations and sometimes pain, with very little appreciable effect upon the organ it was wished to influence, and which possibly was situated in some remote part of the body. That is one of the reasons why the faradic machines, as often employed, and battery belts (even if they possessed any virtue) are so totally useless. It is impossible to influence the bladder by passing a current from one hand to the other, or even round the loins. It is also impossible to treat amenorrhœa by electricity by placing a belt round the body above the pelvis. Golding Bird, who, in his lectures,¹ says, "In electricity we possess the only really direct emmenagogue with which the experience of our profession has furnished us," excited the uterus to action by discharging Leyden jars through the pelvis. The currents we at present employ are of much

less tension, and not accompanied by the unpleasant shock inseparable from the use of the Leyden jar, but they are of very little benefit unless applied direct to the uterus, and to treat amenorrhœa by electricity in any other way, is a farce. Electricity does not act as an emmenagogue when applied indiscriminately to the general surface of the body. It may, in this way, sometimes relieve such an affection simply by the improvement of the general health, but not from any direct influence it would have on the uterus. The absurd "electrical appliances" and "electropathic belts" so extensively advertised for "ladies ailments" cannot be too strongly denounced by the profession, as they are a great imposition upon an ignorant public. If it were possible to pass a weak current of electricity through the body, or any part of the body, for an indefinite time, no doubt great tissue-changes would take place. It would be impossible for such a powerful agent—one capable of splitting up all chemical compounds—to be passed through the body without causing great changes. But the skin offers such a resistance to the passage of electricity, that the body may almost be said to be insulated. No weak current, such as is produced by these battery-belts, could pass through the skin. If one pole from the battery-belt be applied to the body, and a galvanometer introduced into the circuit between the body and the other pole, no deflection of the needle can be detected. If the current from these appliances were strong enough to overcome the resistance of the skin, sloughs would, in a short time, be produced at the points of application of the electrodes, a sore first appearing at the point of application of the negative pole. The same objection holds good with regard to the electric brushes; no battery that they can contain could produce a current strong enough to penetrate the skin of the scalp.

I see a number of patients who have been deceived and deprived of their money by purchasing electric belts, and all kinds of articles of dress supposed to possess electrical virtues, and these articles are sold at a most extravagant price. One man had given seventy-two shillings for an electric corset for his wife. I am often asked if there is any healing power in them or not, and if not, why are they allowed to be so extensively advertised? The answer is, because there is no one who has the power to prevent it. But the medical profession might do a great service to the public at large, and prevent an enormous amount of money being uselessly wasted if they would set their faces at once against this species of imposture, and explain to their patients the utter inutility of all electropathic belts, corsets, hair and tooth brushes, etc., etc. There are several kinds of electrical appliances of this description, one being a collection of bits of magnetised iron, sewn in between two layers of flannel, and another possessing one or more hermetically sealed galvanic cells, also in some manner attached to the belt. In the first place it has not been proved that magnets have any influence whatever on the human body when brought within the field of their attraction. Professor McKendrick, of Glasgow, in his address before the British Association for the Advancement of Science in 1883, said that "all attempts to influence the living body by magnets had no rational basis. He had tested this question by powerful electro-magnets, and had not been able to detect that they had the slightest influence on any vital phenomena." It is also reported that Professor Charcôt, at Salpêtrière, has placed the heads of patients between the opposite poles of the most powerful magnets that can be

¹ "Lectures on Electricity and Galvanism," delivered before the Royal College of Physicians of London, by Golding Bird, A.M., M.D., 1847.

made, without in any way influencing them. These appliances, containing pieces of magnetised iron, will of course easily influence a magnet when moved in its neighbourhood. And this power of influencing a magnet is generally demonstrated by the seller of this class of goods as an evidence of their power, and of the force they are likely to exercise on the human body. Of the appliances which contain concealed in them one or two small cells, usually the chloride of silver cells, the current which is produced will influence a galvanometer, if directly applied to one, but have no effect whatever on a galvanometer, if the resistance of the human body is interposed. The electromotive force of these cells is usually less than a volt, and the internal resistance high. If the resistance of the human body be taken at 1000 ohms. (a low estimate according to some authorities), it would require at least two cells to be applied, under the most favourable circumstances, to deflect the needle of a galvanometer one milliampère; the lowest measurement used in medical electricity, and not in itself capable of doing any good. One volt is not sufficient to accomplish the electrolysis of water, it cannot overcome the chemical affinity by which oxygen and hydrogen are in this compound held together. Professor Silvanus Thompson, not a medical man, but the Professor of Experimental Physics at University College, Bristol, thus speaks of the misapplication of electricity to medicine, "It is not out of place to enter an earnest caution on this head against the numerous quack doctors who deceive the unwary with magnetic and galvanic 'appliances.' In many cases these much-advertised shams have done incalculable harm; in the very few cases where some fancied good has accrued, the curative agent is probably not magnetism, but flannel."

In a recent number of the *Lancet*, January 7th, 1888, p. 35, "public attention is called to the vendors of 'bogus electrical belts' and other worthless appliances, constructed with the ostensible object of employing electricity as a curative agent." It gives the following description taken from the *Electrical Review* of two of these contrivances, "First we have a specimen of a galvanic generator, which is made thus: a small oval frame, of a bituminous nature, contains a similarly shaped but smaller zinc plate, ornamented in relief with 'lightning flashes.' Placed on this is a copper disc of similar shape, without any separating medium whatever between them. The combination is perfectly dry, and we need scarcely say that the apparatus sent to us is absolutely useless. The second is a magnetic appliance, which may be a so-called chest protector or anything else. Sewn up in a semi-circular piece of silk we find twelve feebly-magnetised pieces of crinoline steel, and this is all. Yet the price of the article is said to be thirty-five shillings."

I cannot too strongly call upon the profession to discountenance, in every possible way, the sham electrical appliances thus exposed by the *Lancet*. How can the public know unless the profession teaches them? If the profession is silent in denouncing such a gigantic abuse, as it has now become; can the public otherwise but think that the profession believes that these appliances do possess some virtue, otherwise they would not allow such a fraud to continue?

There is no way of applying electricity for curative purposes except by applying it locally and intelligently for the particular affection it is intended to relieve. Its application should not pass out of skilled hands. If, in certain

cases, a medical man should, after instructing a nurse, allow her to apply it, as in a case of infantile paralysis, which requires the treatment every day for months, he should still hold himself responsible for the treatment, and from time to time see that it is being carried out properly. There are so many points at which electrical treatment may break down, that it is impossible to prescribe it for the public for self-application, without bringing the whole method into disrepute. In these cases of infantile paralysis, to which I have alluded, where parents are seldom able to afford the expense of the continual application of electricity by a qualified man, I have found the most absurd mistakes occur, even when a nurse has been daily instructed in the mode of application. Parents have complained that they see little improvement in their children, and on examining the battery, it is found that there is no current generated; possibly there has been no current passing for weeks, but the nurse has been diligently rubbing the leg daily with the electrodes attached to the battery. At another time, the nurse is asked to go through her usual performance, to show how she does it, and it is found that she has been diligently rubbing the inside of the leg from the time she was first instructed, when the region of the perone muscles and tibialis anticus had been particularly pointed out. Many of these mistakes occur with adults. They mix up the positive and negative poles, or, when electricity is advised for some abdominal complaint, they buy a magneto-electro machine, hold the two handles, and allow a very unpleasant current to pass from one arm to the other, the rest of the body being left almost completely out of the circuit. As no beneficial result follows, they lose their faith in electricity.

There are some of its applications which certainly ought never to pass out of the hands of legally qualified medical men. Instruction in the application of electricity, and schools for massage and electricity, are now advertised weekly. Men and women, without any qualification whatever, are instructed to become skilled medical electricians, and given certificates. It is impossible to blind our eyes to the fact that the creation of a new class of certified, but medically unqualified electricians opens the door for abuses, and exposes the public to a new, or increased danger of harmful and pernicious quackery. It is true that medical men cannot afford the time, or perform the drudgery required for the daily application of electricity, but it would be safer, if each medical man understood the mode of application, that he should instruct some relative or nurse of the patient to apply it in any particular case, rather than educate a new class of purely irresponsible electricians, who would have no sufficient general knowledge to guide them aright, no restraining professional responsibility, and a constantly present inducement to recommend electrical treatment, in and out of season, and for all sorts and conditions of diseases, whether such treatment would be suitable or the reverse.

For the purely surgical applications of electricity, a technical knowledge of the subject, and an intimate acquaintance with the manner of using the different forms of batteries is the more essential. The use of electricity in gynaecological practice has lately excited a considerable amount of attention, in consequence of the discussions which have arisen concerning Dr. Apostoli's electrical treatment of uterine fibroids. I know, from the number of applications I have had from members of the profession, asking for details of the operation, the best batteries to use, etc., etc., that an indiscriminate application of this remedy is being made by men, without

¹ "Elementary Lessons on Electricity and Magnetism," by Silvanus P. Thompson. Macmillan & Co., London, 1883. p. 189.

the slightest previous knowledge of electricity. The difficulties and dangers connected with the treatment of uterine diseases by electricity are as numerous, though fortunately, perhaps, not so dangerous, as those connected with abdominal surgery. In the hands of some three or four surgeons the death rate, from abdominal section, is very low; but the entire death rate is high enough to make the profession anxious to find some alternative mode of treatment. If abdominal surgery were as universally practised as electrical treatment promises to be, the death rate would be appalling. The many points at which accidents may occur, and mistakes be made in electrical treatment, greatly outnumber the chances of failure in abdominal section, as the batteries and apparatus used in the former are so complicated. The use of the wrong pole in electrical treatment may be followed by most disastrous results; and the chances of the wrong pole being used are very numerous, sometimes even escaping the vigilance of the most experienced. The commutator of the battery may have been arranged wrongly by the instrument maker; the galvanometer may have been inserted on the wrong side of the circuit; the current may have to be arrested during an operation, and the commutator reversed by accident through the negligence or ignorance of an assistant. One operation may have required the use of the positive pole, and the next of the negative, and the necessary alterations in the battery have escaped notice. All these accidents have occurred within the knowledge of the author. I write with a sense of the strongest responsibility when I warn the profession against the indiscriminate use of electricity, and its indiscriminate use by those who have not a thorough knowledge of its action, and of the proper way of applying it, and of the construction of batteries. I have seen part of the mucous membrane of the urethra torn off and followed by profuse hæmorrhage by the use of the positive pole in the treatment of stricture. I know of a case where the patient suffered from such extreme collapse after a similar operation, that the surgeon for a time was fearful as to the result. The collapse was produced, either from the current being used too strong, or when strong, suddenly broken. I have been upbraided by a surgeon for advocating the treatment of stricture of the urethra by electrolysis, because in two cases he had set up most intractable cystitis by not cutting off the current after his electrode had passed the stricture, but by passing it on and electrolysing the coats of the bladder; and yet, when properly performed, electrolysis is the best mode of treating stricture. I have seen a patient disfigured for life by the too energetic use of the wrong pole, in treating a hairy mole on the face. In another case, an abscess or slough was produced in the upper part of the pharynx, accompanied by the most intolerable earache, by the use of the wrong pole in an attempt to electrolyse the Eustachian tube. Most profound collapse has been caused by an assistant uncoupling one of the electrodes after the electrolysis of a uterine fibroid, and before the current had been gradually reduced in strength. Very painful and disagreeable shocks have been produced when treating the same affection, by the battery having been sent home by the instrument maker with the zinc of one couple of elements placed in the wrong cell; and in another instance, by the battery being sent home with the fluid omitted from one cell. A case has been published where no doubt the woman's life was in jeopardy by the sloughing of a tumour produced by the use of a too strong current. I mentioned in my paper, read at Dublin, the difficulties, though not

serious, which followed the use of the wrong pole in the treatment of lachrymal obstruction. I could greatly extend this list of the dangers and difficulties connected with electrical treatment, but I have said enough to show that it should not be undertaken without a thorough knowledge of the apparatus to be used, and the mode of using it.

Objections have been brought forward to making a specialty of the practice of, or treatment by, electricity. It has been said that electricity is only a therapeutic agent, which is prescribed in certain cases by the physician or surgeon in the same way as any other suitable remedy might be ordered. That it would be just as reasonable to appoint an administrator of quinine, or any other individual drug, as an administrator of electricity. That every physician and surgeon is supposed to understand the therapeutical uses of electricity, and to be able to administer it, but that some individual is appointed to administer it for him, because he has not time to administer it himself. That the administrator should exercise no discretion as to the form of electricity to be employed, and the manner it should be administered, but should simply carry out the prescription as the dispenser does in the matter of drugs.

All common sense men will at once see that this contention is absurd. The technical knowledge required, involving one entire branch of physical science; the number and complicity of the apparatus used; the experience and dexterity necessary for their efficient employment, and the numerous practical details connected with the different methods, necessitate that this special branch of medical practice should be studied and advanced by professional men who devote themselves to its practice. And above all to rescue this branch of medicine from the hands of charlatans and quacks who have thriven on it for so long, it is necessary that it should be given into the hands of those only who have had a thorough previous training in medicine and surgery, and who can be implicitly trusted by their professional brethren. The prejudice against electricity will gradually disappear if it is never prescribed for cases that can be better treated by other means, but there are so many complaints for which electricity is the most useful curative agent, that it is quite necessary that every medical practitioner should have a general knowledge of its uses, and the varied ways in which it can be employed.

SACCHARINE.

BY ALFRED J. H. CRESPI.

IN Sir Henry Roscoe's masterly review of Chemistry at Manchester, a passage that struck many of his readers with surprise was the one in which he spoke of saccharine, the curious sweetening agent, 250, or it is now said, 300 times as sweet as ordinary cane sugar. Most people knew that the progress of chemical science has of late years been rapid beyond all precedent, and that coal-tar had been the mine from which the modern chemist has obtained colours, scents, and flavours, that had almost revolutionised the arts, and increased the elegancies and comforts of life. But few people knew that the ardent chemist could almost see a time when many valuable adjuncts to human food would be built up in the laboratory, and in any quantity required. There is a great difference between analysing a food and building it up from its very foundation, and while everyone knew that the chemist was able to take to pieces most of the foods in common use and find out their com-

ponent parts, it was not as commonly known that it was becoming possible to take the different ingredients, put them together, and manufacture in the laboratory a something indistinguishable from the finished product of nature's own providing. The triumphs of analytical chemistry were complete before those of synthetical chemistry filled the eager student of science with hope, and here it is that the greatest and most brilliant promise seems to be awaiting him. Is it going too far to prophesy that, judging from what has been done, remembering, too, that the goal of yesterday is reached to-day and left far behind next week, it will be possible and easy, too, in our own day, to manufacture wholesale many of those vegetable foods that have become necessities of life to us? There seems hardly any limit to what chemistry may do, and a young man of real genius and fixity of purpose, who wanted a field vast enough for all his energies and for the longest life, would find none to compare with chemical science. There labour cannot be wasted. A man may immortalise himself by carefully examining what other people throw away, and there is nothing so commonplace, so familiar, that a careful examination of it may not lead to great discoveries pregnant with wonders. Every year fresh plants are being brought to England, fresh fruits and vegetable products are made known, and it requires no very deep knowledge of what has been done, and of what is now taking place to justify the assertion that before the present century has run its course chemistry will have enriched the world with products that for usefulness, potency, and cheapness, will transcend nearly everything that is at the present time within the reach and at the command of man.

The chemist has long possessed chemical agents whose potency might well fill the mind with awe: for instance, one grain of the ammoniacal hypo-sulphite of silver will make 32,000 grains of water intensely sweet, while one grain of strychnine will make one pint of water bitter. But the sweetening properties of this silver salt were only a scientific fact of little use in practical life. Some years ago, however, Dr. Fahlberg, as the fruit of eight years' incessant work and dauntless perseverance, succeeded in converting saccharine, a singular derivation of coal-tar, and quite unconnected with the silver salt named above, from a mere laboratory curiosity into a commercial product, and perhaps Sir Henry Roscoe, one of the most competent judges in the world, did not go too far when he called saccharine "the most remarkable of all the marvellous products of the coal-tar industry."

Saccharine has been attracting the attention of medical men, and according to the medical papers, which are, however, always rather sanguine, will prove invaluable in covering the nauseous and loathsome taste of some of those powerful new medicines with which science has enriched the Pharmacopœia, and which, although useful beyond all expectation are sometimes most unpalatable, or, indeed, like cascara sagrada, so nauseous that many sufferers rather bear the ills they know than face the still more unpleasant ill of being half poisoned by the foul smelling and disgusting remedy.

I shall not attempt to describe the steps of manufacture of saccharine, nor shall I perplex myself and alarm the reader by half a page of chemical symbols, which another advance in chemistry may cause to be abandoned. Suffice it to say that saccharine, or benzoyl sulphonic imide, is a white amorphous powder, which when examined under the microscope is found to have a distinct crystalline

appearance. It is intensely sweet, although when tasted in its pure form is not nearly so overpoweringly sweet as one would expect from the descriptions given in the papers. This is at first disappointing, but the discoverer stated at Manchester at the British Association gathering there, and there is nothing improbable in his explanation, that the intensity of the sweet flavour gave rise to so acute an action on the nerves of taste that it deadens them, in the same manner as too powerful a light will dazzle rather than assist vision. Saccharine must, therefore, be looked upon as an essence, which, to be of practical use, must be freely diluted, and in this respect it is analogous to vanillin, another of the recently discovered derivatives of coal tar, which is superseding the once familiar natural vegetable product, vanilla, as a flavouring material.

In cold water saccharine is only slightly soluble; in water of the temperature of 120° Fahr., it is only moderately soluble; while even in boiling water it is not perfectly soluble, but when the solution is neutralised, and carbonate of soda or carbonate of potash is added to it, the solubility is greatly increased. When saccharine is added to a solution of carbonate of potash, or of carbonate of soda, carbonic acid is freely given off, and a compound of soda or potash salts with saccharine is formed. It is found that these salts are nearly as sweet as saccharine itself, and as they are soluble they are far more convenient to use. One tabloid is fairly equivalent to a lump of white sugar. I find that it is better to put the tabloid into the cup, and then add the hot coffee or tea, and finally the milk. In a week we would get used to saccharine tabloids, and not miss the more familiar, though hardly more palatable, cane or beet-root sugar.

Alcohol, which will dissolve so many substances on which water alone will hardly act at all, will also dissolve saccharine, and no doubt in time the manufacturer of pure unadulterated sweet wines, cordials, and liqueurs, will not forget to add it to his armoury. Mosso has carefully investigated the subject, and finds that one gallon of ten per cent. alcohol will dissolve 378.7 grains of saccharine; one gallon of 40 per cent. alcohol will take up 1391.6 grains; one of 80 per cent. will hold 2250.5; while absolute alcohol will only suspend 2118.9 grains. The reader will notice that an 80 per cent. mixture of alcohol and water takes up the largest amount of saccharine; it is, by the way, often curious, but true, that the strongest solvent, as at first sight it appears, answers worse than a weaker form of the same solvent. Saccharine is also abundantly soluble in warm glycerine. At a temperature of 224° Fahr. saccharine melts, and then is partially decomposed and gives off a characteristic odour. Professor Stutzer, of Bonn, tells us that one grain of saccharine will distinctly sweeten 70,000 grains of pure distilled water.

Saccharine is not a fermentable sugar, and will therefore certainly soon come into common use in the treatment of many diseases, and will be used in many cases in which the palate craves for sweets, but in which ordinary cane sugar cannot be permitted without distinct danger to the sufferer. Still more, to exalt the claims of saccharine to attention, Aduco, Mosso, Stutzer, and Stadelman, all assure us that it is antiseptic, and it is stated not to have any action on ptyalin, diastase, and the digestive functions of the human economy, and passes unchanged from the system.

It is quite a relief to find that it is not expected to drive cane sugar out of the field: that would indeed have been a

bitter pill to swallow, but there can be no doubt that it will, to some extent, enter into formidable competition with it, especially in the making of confectionery and preserves, and sweetmeats are being prepared that, while not less palatable than those we are accustomed to, are decidedly less objectionable. But I must pause, leaving unsaid much that is claimed for saccharine—that truly marvellous product of modern chemistry.

CASE OF CEREBRAL ABSCESS.

By J. JOHNSTON, M.D. EDIN., L.S.A.,

BOLTON.

THE following brief notes of a case of this somewhat rare affection may be of interest:—On September 6th, 1887, I was called in to see M. W—, a well-developed and previously healthy girl, aged thirteen years, whose father had died of consumption. She was suffering from intense diffused headache, intolerance of light, dilated pupils, high temperature, quick bounding pulse, sleeplessness, sickness, and constipation. After persisting for four days, these acute symptoms gradually subsided, the headache became localized to the left side, and a slight discharge of semi-purulent matter came from the left ear. Next day (September 11th) the discharge from the ear had ceased, and the patient was suddenly seized with a convulsion of three hours' duration, affecting the right side of the head, face, trunk, and the right arm and leg. This was followed by a succession of milder convulsions, affecting the right side, varying in duration from an hour to ten minutes, but gradually diminishing in force and frequency, until they ceased altogether on the third day after commencing (September 14th). Upon their cessation it was found that the patient was hemiplegic on the right side and completely aphasic. There was no ptosis, no inequality of the pupils, nor any loss of consciousness, except during the convulsions. The acute symptoms had now subsided, the pulse and temperature being almost normal, but the left-sided headache continued at times to be very severe. During the next three days there was a gradual, but decided improvement in her condition, the hemiplegia disappearing, and the aphasia improving so much that the patient could utter little words, such as "mother," "oh my," etc. She also partook freely of nourishment, and never lost consciousness, nor was there any recurrence of the convulsions. The pain upon the left side of the head ebbed and flowed, being at intervals very agonising, and only controlled by strong anodynes, etc. In spite of the apparent improvement, she gradually lost her strength, and died quietly in the early morning of September 19th, conscious to the last.

The *post-mortem* examination revealed a large collection—about three ounces—of yellow, creamy, semi-putrid pus in a cavity situated between the *dura mater* and the arachnoid, just over the left fissure of Rolando, and extending from the longitudinal sinus down to the base of the brain. Some of the pus had found its way into the longitudinal fissure above, and into the upper portion of the spinal canal below. The site of the abscess was marked by a distinct ovoid depression upon the surface of the brain, measuring about three inches by two. The arachnoid and the substance of the brain beneath the abscess were anæmic, while on the right side they were much congested. The substance of the *dura mater* covering the lower part of the abscess cavity was found to be very much thickened and infiltrated with a mass of tubercular material. As we were

only allowed to open the head, the condition of the other organs could not be ascertained.

NOTE.—Although the apparent improvement seemed to cast a doubt upon the diagnosis to which the symptoms pointed, I should not hesitate in any future similar case to trephine, as the only chance of saving the patient's life.

TREATMENT OF WHOOPING COUGH.

By E. G. SIMPSON, L.R.C.P., ETC.,

CIVIL SURGEON, OUDH.

THIS epidemic occurred in the Sihsagor district, Upper Assam, amongst the children of a batch of Ooran coolies, and was confined to them alone, although they were living in the midst of Bengalese, and other natives from the north-west of India. Twenty-three cases constituted the whole epidemic, and held fast to a group of some twenty houses, occupied by the same caste and tribe. No adults were attacked. Three methods of treatment were adopted, with results as follows:—One case died, a child aged seven years, who was suffering from dysentery, and was in a weakly state when attacked with the cough.

<p>Rx Tr. belladonnæ, ℥i. to iij. Vin. ipecac., ℥ij. to v. Mucil. acaciæ, 3 ss. to 3 i. Syr. simplicis. Aq. camph., aa ad. 3 i. to 3 ij. Every three hours.</p>	<p>Males, 3 Females, 1 } 4</p>	4 to 7.	1	..	<p>Duration of disease, 40 to 90 days.</p>
		2 to 4.	
		1 to 2.	1	1	
		1 year.	1	..	
		Under	Males	Females	
<p>Alum ½ to 2 grain powders every hour up to 12 doses a day.</p>	<p>Males, 2 Females, 3 } 5</p>	4 to 7.	..	1	<p>Duration of disease, 40 to 90 days.</p>
		2 to 4.	..	1	
		1 to 2.	1	..	
		1 year.	1	1	
		Under	Males	Females	
<p>Rx Acid carbolic, ℥i. to ij. Vin. ipecac., ℥ij. to v. Acaciæ gummi, grs. v. to x. Syr. simplicis, 3 ss. to 3 i. Aq. camph., ad. 3 i. to 3 ij. Every three hours.</p>	<p>Treated—Males, 6 Females, 7 } 13</p>	4 to 7.	1	2	<p>Duration of disease, 14 to 18 days.</p>
		2 to 4.	1	..	
		1 to 2.	2	2	
		1 year.	2	3	
		Under	Males	Females	

The case of dysentery with whooping cough was treated chiefly for the former disease, so is not given in the above tables. The treatment of the first cases was taken up in rotation, but when it was found that the carbolic acid acted like a charm, the other two methods were given up.

Remarks.—I have treated altogether 240 cases of this disease, and with the exception of the case noted, have had no deaths, showing that the disease is not a fatal one *per se*, unless complications arise, or another disease exists. Symptoms are invariably preceded by fever and catarrh, leaving an irritable state of the mucous membrane, the cause of paroxysms and whoop being an irritated condition of the ends of the pharyngeal branches of pneumo-gastric nerve. The frequency of the paroxysms depend on the degree of irritability, more or less varied by the use of the throat in talking, etc., and the time taken in generation of nerve force. Carbolic acid was used as a nervine sedative, with a result that speaks for itself.

All the other cases were treated by most of the various methods recommended, but none of those in any way approached the decided and quick benefit derived from carbolic acid. When a child of about seven years of age, I had whooping cough, and the medical attendant prescribed for me every evening tartar emetic to induce emesis. *Cui bono?* I do not recollect it, but I looked upon it as a severe punishment.

In Lancaster a good many of the people have an idea that the inhalation of gas is beneficial, and advise their children afflicted with whooping cough to rush into gas manufacturies, but the results are doubtful, for it appeared to me that the disease hung on for three months or more.

IS CRANIOTOMY JUSTIFIABLE?

By T. READMAN, L.R.C.P., ETC.,

FELLOW OF THE BRITISH GYNÆCOLOGICAL SOCIETY.

[It was originally intended that the following paper should be read before the Obstetrical Society of London. It was presented by one of the Society's most eminent Fellows, and submitted to the Referees, who advised that it should be read and published. In spite of their Referees' decision, the Council refused to have it read. Of course, it is a well-known fact that the Obstetrical Society is the seat of the head and front of the offending in this matter.]

WERE I about to obtrude my own ideas and opinions upon you, I am afraid I should sorely lack the courage necessary to enable me to do so. I merely wish to place before you old facts in a new form, to look at this important question in a new light—in the light of modern statistics.

Having regard to the general advance of medical and surgical science, especially during the last twenty years, is it not surprising that an operation so pernicious and disgusting in itself, so repulsive and unscientific in its procedure, and so fatal and disappointing in its results, should still be recognised and sanctioned by the profession, and should still be taught in our medical schools? Now when abdominal surgery has been stripped of most of the horrors with which twenty years ago it was enshrouded, may we not hope that the present generation may see the perforator laid aside, and more rational and scientific operations substituted for this barbarous proceeding? Does it not seem monstrous that, when we have a thoroughly scientific and tolerably safe alternative, the taking away in the most brutal manner the life of an innocent child should still be preferred? Is such conduct consistent with the great fundamental law of Christian ethics, that evil is not to be done that good may follow? Dr. Meadows, in a paper which he read before the British Gynæcological

Society, said: "My opinion is that the whole tendency of modern midwifery practice is setting in very decidedly in the direction of absolutely and entirely abolishing this most abominable, unscientific, and brutal proceeding, and I am strongly of opinion that, if not in our day, at least before another generation of gynæcologists shall have passed away, the practice of deliberately sacrificing a human life will be regarded as wholly unwarrantable, and not to be contemplated for a single moment in the face of other more scientific, more humane, and far more successful modes of treatment."

Is it right to kill the child when this is considered a necessary means of saving the mother? The answer to this serious question constitutes the answer to the chief argument now-a-days used in favour of craniotomy. We are taught to sacrifice one life to secure the safety of another, the mother's safety being purchased by the destruction of her child. On this point allow me to quote a few words of Mr. Lawson Tait; he says: "The child has no one to look after its interests, and it is the only person in the relations whose vote concerning its presence has not been asked for or obtained. In this defenceless position it therefore is peculiarly deserving of consideration, and it is a terrible responsibility for anyone to undertake its deliberate destruction."

There is not a single argument from authority or reason to justify the killing of a guiltless individual. If the child was born, who would dare to plunge an instrument into its brain, even if its death—if we could suppose such a state of things—was considered necessary to save the life of the mother? It is morally murder in either case, for in either case you are taking away a life. But surely, says the craniotomist, it is better to save one life than to lose both, and of the two we should preserve that which is far the more precious and important. But we answer, who is to judge which is the more precious and important? Churchill says: "No man dare make such a choice, for we have neither the necessary knowledge, nor the right, nor the authority to decide which is the more important life, and the best worth preserving." If we may take away one life to save another, if we may sacrifice the less important to save the more precious, we may of course occasionally kill the mother to save the child, because in our limited judgment there are many circumstances in which the life of the latter is much more precious and important than that of the former. All wives and mothers are not perfect. The only just conclusion we can come to is that we have as much right to kill the mother to save the child, as we have to kill the child to save the mother; in other words, we have no right or authority to deprive any human being of life. "Human life is held at the will of one Supreme Being alone, and to no human hand is delegated the power of destroying it."

As bearing upon this part of the question, I am about to quote *in extenso* the summing up of Mr. Justice Stephens in the case of the Queen v. Cocks, Evans, Gleaves, and Webster, which I hope will be fresh in your memories. I have thought it well to give Justice Stephens' address almost verbatim, because I think it illustrates the state of the law as to the taking away of human life through necessity; there is not a single sentence in the learned judge's remarks which might not be addressed to a surgeon were he on his trial for having performed the operation of craniotomy. These men were charged with causing the death of a Malay sailor known as Hassim, by shooting him while on board the barque,

¹ "The operation of craniotomy consists in plunging an iron instrument into the skull of a human being . . . in the whole range of surgery this is the only operation recognised and sanctioned by the profession with the avowed intention of destroying life."—*Ramsbotham*.

Lady Douglas, of Glasgow, on a voyage from Australia to England, on April 23rd, 1887.

Mr. Justice Stephens, in summing up, said: "It was the bounden duty of the jury to judge the conduct of the prisoners according to the rules of law he would lay down for them, and which were the rules of rational justice and common sense, making full allowance for the difficulties in which they were placed, but requiring them at the same time to behave with courage and humanity. Two of the four things alleged in their defence were that they were excused by necessity, and that they acted in self defence. It was hardly possible to put a case where the taking away of human life through necessity would apply, especially after the decision in the case of the *Queen v. Dudley and Stephens*, where the fact of two men in an open boat in mid-ocean killing a boy to preserve their own lives by eating his body, was held to be murder. An idea which ran through the defence was that the captain and the crew had a right to take this poor man's life because it was more or less inconvenient to them, and because they came to an agreement to shoot him. A more terrible claim, one more emphatically to be repudiated and declared to be unfounded, he could not imagine. To say that the captain and his crew meeting together in a cabin had the power to declare that one should be shot because he was dangerous, that one not being heard at all, was a monstrous doctrine. The jury must beware that their verdict did not encourage timid men under circumstances of difficulty to get out of their difficulties by taking away the lives of some of their number. Before they could excuse what was done, they must be convinced that the men on board this ship were in greater danger than the two men who killed the boy on the open sea to preserve their own lives."

The jury, after a deliberation of two hours and a half, returned with a verdict of wilful murder. Mr. Justice Stephens, in his remarks in passing sentence of death on all the accused, said: "The jury had returned the only verdict they could possibly have returned in this case—namely, that you and each of you were guilty of wilful murder. I cannot help saying that it appears to me that there was a want both of humanity and courage in the line of conduct you deliberately pursued."

Craniotomists destroy one life to save another; that is the plea of necessity; but, in the above case, in the prisoners opinion, they destroyed one life to save the lives of all the crew. For the man Hassim was located in the coal hole; he was possessed of matches, with which he might any time have set fire to the ship, and a crowbar and knife, by means of which he could have made a hole in the ship and sunk her and her crew. Yet the accused were found guilty of wilful murder, and sentenced to death.

There is not the slightest doubt that craniotomy is often practised without necessity. Mr. Lawson Tait speaks strongly on this point, "I am perfectly certain," he says, "from what I see in publications, and from what I hear from the lips of men in practice, that a perfectly unjustifiable amount of child-murder by craniotomy is practised." Dr. Churchill wishes it to be impressed upon every practitioner that he who destroys the child without due evidence that this is *his only means* of saving the mother, is *guilty of murder*.

Taking them in order the first alternative to craniotomy is the induction of premature labour; for this to become really effective we should have to adopt some such method as that proposed by Dr. Edis. He advocates strongly the

necessity of examining every patient at least two months before the time of her expected confinement, in order to determine whether parturition was likely to be attended by any unusual risks and difficulties. Of course I am aware that this plan is pursued by many medical men, but in order to make it really thorough in its application it must be universally adopted. I should like to ask you if you do not think that any medical man, having charge of a pregnant women whose pelvis he knows or suspects to be deformed, or when it has been proved by actual experience and to an absolute demonstration that a full-sized head cannot be born alive, would not be guilty of a grave breach of duty, were he—knowing full well the difficulties and dangers he would have to contend with—wilfully to allow the patient to go beyond the seventh month of pregnancy? And yet how often is this precaution neglected! To this operation, provided it is not undertaken before the child has obtained sufficient maturity to enable it to live outside it's mother's womb, there can be no objection, because it allows a fair chance of life to both mother and child. If this line of conduct were strictly followed out, if, when we have the faintest suspicion of a deformed pelvis, we would take the precaution to ascertain whether a full-sized head can or cannot pass through the pelvis, we should probably very much reduce the number of cases in which the question we are discussing, would have to be broached.

If the pregnancy is too far advanced for the induction of premature labour to be of any advantage, our only alternative is abdominal section. To the term Cæsarean section I have objections; it is associated in the minds of English surgeons with statistics denoting a large percentage of failures. Ordinary practitioners, as a rule, look horror-stricken at the bare mention of the name, they are shocked at the very idea of touching the abdominal wall with a knife. How is it that British and foreign statistics differ so widely. The reason is not far to seek. It is simply because Cæsarean section never enters the minds of British surgeons, until every other means, the perforator included, have been tried, until the woman lies moribund; then perhaps the surgeon—brave man!—finds courage enough to do abdominal section. But under these circumstances, what other than a fatal result could possibly be expected? How can a fair estimate of the worth of an operation be formed on statistics such as these? To quote Dr. Kinkead's eloquent remarks, "Then when the patient is exhausted by pain and frequent expulsive efforts; when structural change, produced by protracted uterine contractions, has taken place; when she sinks from shock or falls a victim to the sequelæ, almost necessarily resulting—the case is quoted as an additional item in the sum total testifying to the essentially fatal nature of Cæsarean section."

Dr. Harris and Dr. Säger report the result of thirty-one operations performed, after what is known as the Säger method; this report brings the subject up to June, 1886. Of these thirty-one operations twenty-three were performed in Germany, four in Austria, two in France, and two in Italy. The maternal mortality in these cases amounts to a little over twenty-one per cent., and in the case of the children a mortality of seven per cent., in other words twenty-four out of thirty-one mothers were saved, while twenty-nine out of thirty-one children survived.

Dr. Meadows, in quoting these statistics, remarks, "I venture to affirm that craniotomy in comparison with this operation becomes at once almost unjustifiable; for these figures show that, as regards the maternal mortality, it is

little, if at all, more dangerous than craniotomy, and in the latter case all the children would be sacrificed, while in the former twenty-nine out of thirty-one, or about ninety-three per cent. were saved! From July, 1885, to July, 1886, twenty operations have been reported, resulting in the saving of eighteen mothers, giving a maternal mortality of ten per cent., and of the twenty children nineteen were saved, thus bringing down the fetal mortality to five per cent. Nor is the success noted above in any way due to the superior skill of any one operator, they were scattered over the continent, and the thirty-one operations were performed by no less than eighteen different operators. As Dr. Harris remarks, "this success is due to the operation having been elective, and not the *dernier ressort*, and this will be the general result whenever obstetricians shall be made to comprehend the value of an early elective operation."

"Where is craniotomy now?" asks Dr. Meadows in quoting the above. Yes, where indeed. Dr. Harris strikes the keynote of the whole question when he says "this success is due to the operation having been elective and not the *dernier ressort*." Surely these figures will tend somewhat to dispel some of the terrors which abdominal section has for a British practitioner, and to give him a little more courage and determination, will help him to decide whether he shall deliberately take away an innocent life, or whether he shall give to mother and child an equal chance of surviving.

Can anything be more revolting and disgusting than the following case recorded in the *Med. Chirurg. Trans.*, Vol. xii., p. 308, "in which a child lived for forty-six hours after its extraction, although the cerebrum was completely broken down, and about two ounces of brain were taken out. It cried frequently and loudly, passed fæces and urine, and for twelve hours the functions of life seemed to be carried on in the usual healthy manner."

No one I think will deny that it is anything but a universal custom to extract the child by Cæsarean section, should a mother unfortunately die during labour or late in pregnancy. Does it not seem a pity that the moral necessity of extracting the living child from the womb of its dead mother should not be more seriously impressed on the minds of students? Does our code of morals become less stringent as generations pass away? Certain it is that we are not nearly so strict on these points as were the ancient Romans, for their laws prohibited the burial of a woman who had died pregnant "*antequam partus ei excidatur*." Some of the most eminent men owed their lives to the enforcement of this law.

I should like, before concluding, to quote the following summary of Dr. Barnes, in a paper on the alternatives of craniotomy, read in the Section of Obstetric Medicine, at the annual meeting of the British Medical Association, 1886:—

"1. The legitimate aspiration and tendency of science is to eliminate craniotomy on the living and viable child from obstetric practice.

2. The advance of hygienic rule, the improvements in the forceps, in turning, in the induction of labour, and in obstetrics generally, have materially curtailed the field within which craniotomy can be justifiable.

3. In the most extreme degree of pelvic distortion, where delivery *per vias naturales* can only be effected with doubtful success to the mother, Porro's operation is the legitimate alternative for craniotomy, it being understood that the opportunity of inducing abortion has gone by.

4. In less advanced degrees of pelvic contraction, but still incompatible with the delivery of a living child, *per vias naturales*, the opportunity of inducing abortion having gone by, but in which craniotomy would effect delivery with a strong presumption of safety to the mother, the Cæsarean section may be a proper alternative for craniotomy. This is the most debatable point.

5. In minor degrees of contraction, say from three inches to three and a half or three and three quarter inches, the opportunities of inducing labour having gone by, the far greater safety to the mother obtained by craniotomy, and the prospect of living children in future labours, make craniotomy the proper course to adopt.

6. In other emergencies than deformity, as in obstructed labour from ovarian tumour, the alternative to craniotomy is to remove the tumour.

7. In cases of immovable tumour, Porro's operation is the proper alternative.

8. In rupture of the uterus, the child being delivered or not, Porro's operation is the proper alternative. There the interests of the mother and child coincide.

9. In cases of disease or tumours of the uterus obstructing delivery, Porro's operation is the proper alternative.

10. In atresia of the cervix or vagina, Cæsarean section or craniotomy may be necessary, but incisions and gradual dilatation will more frequently be the proper alternatives.

11. When obstruction is due to hydrocephalus or dropsy in the child, embryotomy or tapping is indicated, and decollation when the child is impacted and turning hazardous.

12. In convulsions and hæmorrhages the proper alternatives for craniotomy are found in the more scientific methods of conducting labour under these complications."

With regard to paragraph 5 of the above summary, I am afraid Dr. Barnes has not been correctly reported; he says, craniotomy is justifiable in contractions of $3-3\frac{3}{4}$. I would ask—with all due respect to such high authority—are we then to abolish the use of version and forceps, for we are told, on both Scottish and American authority, to use forceps and version down to three inches at least.

Dr. Lusk gives it as his opinion that, "*under $2\frac{3}{4}$ inches, that is below the limit where premature labour and version are available*, modern methods of Cæsarean section are preferable to craniotomy."

Again, with regard to paragraph 11, we must still maintain, for the reasons I have already given, that no malformation or disease of the child short of death will justify operations involving the destruction of the child. I believe that nothing less than the total abolition of craniotomy will be tolerated when once the profession is brought to view this sacrificial operation in the true light, and when the surprising statistics of modern Cæsarean section and Porro's operation become well known.

So long as surgery teaches and sanctions craniotomy, so long will our profession, which is acknowledged to be of the noblest, labour under the stigma of legalized child-murder. There is no getting out of it, argue as you will, in doing craniotomy, you are committing a murder, for which you have no just excuse; for has not one of our greatest authorities declared that he who destroys the child without due evidence *that this is his only means* of saving the mother is guilty of murder? It will not do now, in the face of modern statistics, to say that you kill the child in its mother's womb because you think that this is the only means of securing the safety of the mother; there are other means you can adopt, and the facts and statistics I

have brought forward show that these will not unduly jeopardize either life, but will give to each a fair and equal chance of survival.

Meadows, Barnes, Tait, Snger, Harris, Tyler-Smith, Kinkead, and others have sounded the death-knell of craniotomy. It will live only to be remembered as an act of barbarism practised in a less enlightened age. Obstetricians of the future will wonder that such a barbarous custom was so long tolerated, that such a blot was allowed to remain to sully the fair name of so noble a profession, whose avowed object it is to save life, and never wilfully to destroy it. Let us bury craniotomy and strive to forget it, forget that the faculty could ever have given its sanction to so revolting a means of securing the safety of the mother.

Far be it from me to think even for a moment that craniotomy was ever wilfully performed without necessity; if I have said anything that has conveyed to your minds an impression to the contrary, I would wish to withdraw it, for I hold no such mean opinion of the honour and morality of the members of the profession to which I have the honour to belong. I firmly believe that medical men, have, as regards this operation, always acted in perfect good faith and according to the best of their understanding.

Do allow me to earnestly and fervently appeal to you to give your most serious consideration to this all important question. Let us hope that the time is not far distant when under the pressure of modern statistics and a more rational consideration of this issue, we may see the total abolition of craniotomy an accomplished fact.

CARDIAC TONICS.

By J. C. WADDELL, M.D.

COMPARISON of the practice of medicine of to-day with that of fifty years ago shows most clearly what may be termed an entire change of front. The practice of fifty years ago was essentially a treatment of results; that of to-day is fundamentally the treatment of ultimate causes. The greatest development in the whole field of medicine has been in the direction of etiology, and the great light which scientific research has shed upon the nature of the conditions occurring in disease has indicated most clearly the line which therapeutics should take. Most especially those researches into the presence of bacilli in the human organism and their development, has proved the enormous power possessed by the vigorous physical constitution, not only in resisting the onset of disease, but also in quelling it, even when established. Disease in a feeble-powered and in a full-powered frame takes ordinarily a different course; and this has been so evident for a long time, that it has been recognised as a cardinal point of successful treatment of the body when suffering from disease, that its powers must be guarded, economised, and developed to the utmost extent. Although in the human economy each organ seems dependent to some extent upon all the others, yet the prime place must necessarily be accorded to the organs of circulation, inasmuch as while so long as the circulation of the blood remains perfect and unimpaired, almost any of the other functions of the system may be incomplete, or any of the other organs affected, without necessarily affecting vitality; but when the circulation of the blood becomes imperfect, or is arrested, then everything is affected, and vitality is imperilled. For this reason the possession of means to enable us to deal directly with the heart and its functions has long

been an eager desideratum to the physician; the power to stimulate or to depress, to increase force or diminish it, to increase tone or lessen it, are ardently sought and longed for. Remedies which will affect the tone of the heart and organs of circulation are, for obvious reasons, those which are most needed, and, unfortunately, we have but few.

Digitalis is the best known and most familiar, but even this is of comparatively recent date. Until about 1860 it was little more than barely known to the profession, and since that time experience has proved so many dangers connected with its action, that the need of remedies which will produce an equal effect without its cumulative tendency has become almost imperative. The therapeutics of to-day gyrate round one central point, that of preserving the balance of power of the circulation of the blood. There is a certain standard which cannot be either exceeded or diminished without some disturbance of the whole organisation. This healthy standard may be best described by the expression "tone." Therapeutically, drugs acting upon the circulation may be divided into six groups.

(a) *Cardiac Stimulants*.—These act rapidly by increasing force and frequency, and counteracting depression. Ammonia and alcohol may be regarded as typical.

(b) *Vascular Stimulants*.—These are defined by Lauder Brunton as "substances which cause dilatation of the peripheral vessels, and thus render the flow of blood through them more rapid;" they do not, however, increase the contractile power of the vessels, nor the activity of the vaso-motor centres. Heat, alcohol, and some diaphoretics are typical of this group.

(c) *Cardiac Tonics*.—"These are drugs which have no perceptible immediate action on the heart, but when given for a little while, render its beats much more powerful, though much slower" (Lauder Brunton). The most important are—digitalis, strophanthus, convallaria, and viscum album.

(d) *Vascular Tonics* cause increased contraction of arterioles or capillaries—raise blood pressure and influence to a considerable extent the amount of lymph poured out into or absorbed from the tissues. The most important are—digitalis, with the other cardiac tonics mentioned, and iron and strychnia.

(e) *Cardiac Sedatives*, which lessen force and frequency of heart's action, and are useful in violent action of the heart, or for rendering the pulse slower. The most important are—aconite, veratria, and antimony.

(f) *Vascular Sedatives* increase the contraction of the vessels, and lessen the flow of the blood through them, and are useful chiefly in local inflammation or to arrest hæmorrhage. The most important are—cold, ergot, hamamelis, acetate of lead, etc.

It is with the groups of cardiac and vascular tonics that we are now concerned. All cardiac tonics may be considered as indirect vascular tonics, and, therefore, in the following remarks we shall not consider them separately. In practice the cases in which we find that cardiac tonics are serviceable may be divided into two classes—those in which the heart is feeble or inefficient in action, but free from valvular lesion and those in which there exists a lesion or important structural change. The former constitute the most frequent, and practically the most important. Where a lesion exists the patient can be brought to understand why the general health should be affected, and any of the well-known symptoms of "heart disease" be present; but where no lesion exists, where there is no organic mischief but merely functional derangement, it is often very difficult

to keep a patient's mind easy and prevent them rushing from one practitioner to another, in the desire to obtain relief or cure. Further, when the general health and physical powers have become enfeebled, it is very important for the practitioner to possess the means of getting his patient rapidly well. Or during the course of some other ailment, which depreciates vital power—it is most important to possess means which will act as support or stimulus to the flagging circulation. Such are some of the points which appeal most strongly to the minds of general practitioners, who naturally wish to know what will most readily and certainly effect their purpose, without entailing profound study of details or considerations as to motor-ganglia, vagus centre, accelerating centre, and so on. Cardiac tonics act upon the cardiac muscle and render its contraction slower and stronger. This is their usual effect when given in moderate doses; when given in larger doses they produce effects of a different, and in some instances of a dangerous and undesirable, character—to be referred to later in connection with each of the drugs dealt with.

The cases for which cardiac tonics are most desired may be summed up under the term "weak heart." This may occur under a variety of conditions, such as anæmia, chlorosis, neurotic idiosyncrasy, after exhausting affections such as acute fevers, habitual over-exertion, alcoholic and nicotine asthenia, chronic pulmonary complaints, more especially indurations of the lung. Weakness of the heart is not necessarily associated with, but is frequently accompanied by, dilatation and functional, or, as we may term it, asthenic incompetency of valves. As a rule, this class of drugs will be found most serviceable in cases where the propelling power of the left ventricle is defective. This condition may be due to asthenia of the ventricles, without any form of lesion, to irregular action of the other cavities, and, of course, to valvular lesions of various kinds. Whenever the venous system is gorged, cardiac tonics are serviceable by strengthening the action of the muscle. They increase the systolic power of the left ventricle, which, propelling a greater quantity of blood into the aorta, enables a longer diastole to occur, with the inevitable result that the lungs, right side of the heart, and venous system generally, are freed from over-pressure.

The principal cardiac tonics known to us at present are, according to Lauder Brunton—

<i>Digitalis.</i>	<i>Adonis Vernalis.</i>
Digitalin.	Adonidin.
Digitalein.	<i>Squills.</i>
Digitoxin.	Scillain.
<i>Erythrophlaxum (Casca).</i>	<i>Helleborein.</i>
Erythrophlocin.	<i>Antiarin.</i>
<i>Strophanthus Hispidus.</i>	<i>Caffeine.</i>
Strophanthin.	<i>Nux Vomica.</i>
<i>Convallaria Majalis.</i>	Strychnine.
Convallamarin.	

To these must be added *Viscum Album*, or Mistletoe.

(To be continued.)

SEPTIC PNEUMONIA.¹

BY FREDERICK H. ALDERSON, M.D.,

LATE PRESIDENT OF THE WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

THE subject that I have selected to read a case upon is one, probably, of interest to all who practise medicine; the consideration of the pathology of septic pneumonia is, perhaps, one particularly calculated to produce a lively and not unprofitable discussion, and is upon a subject, too,

¹Delivered before the West Kent Medico-Chirurgical Society, February 3rd.

that medical men may with honesty form their own opinion from their individual experiences as to the order and specific nature of this very acute disease. In thus calling the attention of this Society to a case, as I believe, of septic pneumonia, I will first describe what I mean by such definition. I desire to differentiate that form of inflammation of the lungs which has its origin in blood-poisoning, *i.e.*, is the result of direct infection, differing from pyæmia, inasmuch as that disease invariably has a local origin, and the lung affection is only one of many subsequent complications, the dire result of a local proximate cause.

Recent able authority has determined that pneumonia is to be regarded as a specific infectious disorder, rather than a disease due to exposure; and the following case, occurring in my practice in the height of summer, and one where the patient was often incurring undoubted risk of infectious exposure, tends to confirm this opinion, although I quite believe with that clinical physician of solid repute, who in a late discussion expressed his confident belief "that if we were for a moment disposed to give up chill as an etiological factor in fibrinous inflammation of the lungs, we shall soon have to come back to it."

William Booth, æt. twenty, died somewhat suddenly at 8 p.m., Monday, July 10th, 1887. W. B. was a pawnbroker's assistant, but did not sleep at the business premises. I obtained the following history of his illness and death from his fellow-assistant, who shared the same bed-room with the deceased. These particulars were confirmed and supplemented by his brother and brother-in-law, who was manager of the business where W. B. was employed:—Charles Edward Cooper told me he was engaged in the same firm as the deceased, and slept in the same bedroom. W. B. left business as usual at 12 o'clock on Saturday night, very tired after a hard day's work, but he did not complain of being ill or of feeling unwell. He coughed occasionally, but not more than usual. He had been much worried in the morning by his master blowing him up because the shop was not open. Cooper noticed on Sunday morning that his face was flushed, and he complained of feeling poorly. His breath appeared quick and short. He got up, but could not eat his breakfast, and said his head ached. He went with his brother—a boy of fourteen, and who had slept in the same bed with him on the previous night—to the public baths, where he had a warm bath. He returned home, and went at once to bed, keeping in bed all day. It was noticed that he was hot and feverish. Cooper was away all Sunday, came home to bed about 12.15 a.m. on Monday morning. He asked him for water, and drank it as if thirsty. He did not disturb him in the night, but on his waking about 7 a.m. he heard deceased breathing very hard, but he was conscious, for he answered him. He at once got up and went for me (my house was about five minutes' walk). I hastily dressed, and returned with him. On our arrival we found W. B. dead. The body was warm, the countenance peaceful, the pupils slightly contracted. A slight rash was noticed on his back and arms, which possibly might have been caused by pressure of laying. Autopsy about thirty hours after death. The slight mottling of the skin that I had observed immediately after death had almost entirely disappeared. The body was clean, well nourished, and apparently that of a healthy, vigorous youth, nails bluish, slight rigidity. About two ounces of clear straw-coloured fluid was found in the pericardium. There was apparently no external pericarditis. The heart was of normal size. The aorta

was much inflamed, especially near the valves. There was slight commencing atheromatous deposit on the anterior valves. The right auricle was rather dilated, the substance of the heart was flabby and soft. The cavities were empty, with the exception of one or two fibrinous clots in right ventricle, white, but not grooved. Lungs were firmly adherent. The pleural cavities were obliterated by old adhesions. The right lung had to be torn away, and was much engorged with dark venous blood. The lower lobes were soft, and easily broken down. The lung floated in water, but not buoyantly. The left lung was congested, but not friable, and less adherent than the right one. The stomach was collapsed and empty. Some discolouration in patches, apparently *post-mortem*. The rugæ were rather large. The spleen was very large and heavy, about three times the usual size. The liver was greatly enlarged, and extended three inches below the level of false ribs. There was no peritonitis; the bowels were healthy, and the kidneys normal.

After the *post-mortem*, I made special enquiries as to his habits. There was no history of intemperance, and as he had lived some time with his brother-in-law and sister, they must have known if he had been either intemperate or unsteady. I had carefully examined him two or three years before his death for a life office, and I noticed there was a want of expansion of his lungs, and he acknowledged he was subject to an occasionally irritating cough, but said he had never been ill, excepting when a child with children's diseases—and how often are these diseases of childhood taken as a matter of course, forgotten by the parents, and too often ignored alike by the patient and the examiner of the life office. Deceased's life was accepted by the Gresham, although allowed to lapse from non-payment of premium.

It is perhaps important to mention that W. B.'s brother-in-law, who was manager at the establishment where he was employed, told me that it was a part of W. B.'s duties to fix the tickets and to examine articles pledged. He also told me that there was a very bad smell in the shop, that was afterwards found to come from an old unused drain, which was situated just under where deceased stood for several hours on the Saturday preceding his death. The manager had several times complained of this smell, and called the attention of the landlord to the unsanitary state of the house.

Infectious pneumonia is more frequent than is, perhaps, generally thought. Very often we have a case of high fever, no rash, hurried breathing, quick pulse, and perhaps diarrhoea, accompanied with fine crepitation at the base of the lungs. Where there is no history to be obtained of cold, and although, perhaps, no positive history of infection, septic origin is a reasonable, and perhaps a probable cause of the illness.

The case I have related—although as to the true character of the disease, is not perhaps to some of you without doubt, but looking at it, as I have at least grounds for, as a case of septic pneumonia—is, perhaps, of some value. For I think the extraneous origin of the disease was evident, *i.e.*, it was a case of blood-poisoning from the very first; and thus in contra-distinction to those authors who infer the auto-genetic origin of the disease, and teach if pneumonia is ever caused by a parasite (and I see no reason why we should doubt the existence of a bacillus pneumonia any more than the bacillus of tubercle or cholera), it is developed in the patient *after* the illness has begun.

Since I have written this paper I notice an interesting paragraph in the *British Medical Journal*, January 28th, page 202, headed, "A New Form of Infectious Pneumonia;" and as the *post-mortem* as well as the clinical history of the case of W. B. corresponds very much with the symptoms mentioned in this paragraph, especially as to the great enlargement of the spleen, and the previous irritating bronchial cough. I will read it to you:—"At the recent Medical Congress in Italy, Professor Cantani presented a communication on a new form of infectious pneumonia which had been observed by him. The clinical history showed broncho-pneumonia, preceded by a diffuse bronchitis, with remittent and very pronounced fever; considerable emaciation, and a great enlargement of spleen. The disease was contagious, and was a primary affection of the bronchi, which extended downwards through the lungs, and sometimes over the pleura, and upwards along the trachea, and even to the larynx. Bacteriological examination revealed the presence of numerous diplococci, and especially streptococci, similar to those found in erysipelas. The pure culture did not, however, produce erysipelas when injected subcutaneously. When they were injected under the skin of a rabbit's ear, only swelling and reddening at the site of puncture were produced. All the cases ran a favourable course."

The points of difference here are: W. B. was not emaciated, but had he lived longer, no doubt he would have been; and apparently his disease was not contagious, or his young brother who slept with him on the Saturday preceding his death, and his fellow-assistant who shared the same bedroom, would have probably contracted the disease. But I have observed that diphtheria, typhoid fever, and septic pneumonia, are, judging from my own personal experience, only in a small degree contagious. Two or three in the same family not infrequently suffer from the same disease at the same time, or nearly at the same time, who have been exposed to the same cause; but the risk of contagion from actual contact is, I think, small. This disease may not infrequently spread rapidly if the cases are crowded together; a space of at least 2,000 or 3,000 cubic feet is probably necessary, or the recovery is at least retarded, and the atmosphere of the sick room may become contaminable and dangerous.

Such is the history of this somewhat sudden death. Have I too hastily assumed the cause was due to septic pneumonia? Might it not with equal accuracy, or even more scientific accuracy, have been due to typhus? Typhoid we are able to exclude from the probable cause, as *there was no peritonitis nor intestinal lesion*. How far had the condition of the heart and aorta any influence as an excitant cause of the pneumonic inflammation? On reflection I was led to give to the coroner septic pneumonia as the more probable *causa mortis*; pneumonia was undoubtedly proved, both by the *post-mortem* and the history of illness as given by the deceased's brother and fellow-assistant. Its septic origin I inferred from the *very large spleen*, and the large and swollen liver, and this opinion was confirmed by the two sources of infection to which he had been exposed, the bad drain and the sorting of probably infected clothing. As a candid observer, and with no wish to conceal facts that are contrary to my own view of thought, I should mention that Dr. Hirsch, Professor of Medicine in the University of Berlin, in his handbook of "Geographical and Historical Pathology," p. 161, gives as his opinion "that the existence of malarial pneumonia, or of a fibrinous inflammation of the lungs, is directly due

to the malarial poison, appear to be doubtful to say the least ;" but on the previous page he writes, " The conjecture that the primary infected pneumonia owe their origin to a variety of infectious matters, or in other words, that there are forms of infective pneumonia differing in their ætiology, cannot be summarily dismissed."

We learn from Dr. Watson Cheyne, p. 301, in the book published lately the new Sydenham Society on "Micro-parasites in Disease," that "Micrococci in the alveolar exudation of acute pneumonia is a constant factor, and that they are found in large numbers in the lymphatics of the affected lungs."

I will conclude this paper with a brief extract from the *Lancet*, of October 30th, 1886, which illustrates, very strikingly I think, the occasional septic origin of acute pneumonia.

UNUSUAL COINCIDENCE.

On the 18th of this month a man and his wife were admitted into St. Thomas' Hospital suffering from acute pneumonia of respectively three and four days' duration. Each was aged thirty-two years. The disease ran an acute course, being little influenced by treatment, and they died at the end of four days within a few hours of each other. At the *post-mortem* examinations, which were made on the same day, acute inflammation of the right lung was found in each ; this had attacked chiefly the base in the case of the man, and the apex in the woman. It would appear that they had left their house, and moved into lodgings only two or three days before the commencement of the disease, on account of the bad smells, making it probable that the disease was of septic origin.

Special Articles.

HEALTH RESORTS OF THE WORLD.

WOODHALL SPA.

THIS old and well-known spa, we are pleased to notice, is now deservedly attracting attention, and promises under the present management to form an important addition to the pleasant, well-conducted home health resorts we are anxious to encourage. Why send all our patients abroad when we have within easy reach such a wealth of health-giving waters at home in Great Britain? Woodhall, according to Dr. Charteris, is a strongly iodurated, bromine spa, with chlorides of calcium, magnesium, potassium, and carbonic acid. The baths are very efficacious in the treatment of chronic rheumatism and secondary syphilis. In some admirable papers in the *British Medical Journal*, Mr. Ernest Hart told us some of the reasons why patients went to Carlsbad, and also why Carlsbad was so attractive. Those who own the Carlsbad waters know their value, and they strive to attract visitors by the comfort and even luxury of the surroundings, by music, buildings, parties, reading rooms, etc.

Woodhall Spa has been in a measure neglected, but now we are assured all this is changed, and we are able to present our readers with an account of some of the improvements already started under the new management.

Barely nine months have elapsed since the present proprietors commenced active business operations. Since then the hotel has been entirely re-modelled, and throughout

beautifully furnished ; the stables which adjoined the hotel have been removed, and the gardens most pleasingly laid out by Mr. Dolby, of Boston, and the whole is now surrounded by a most charming park of seventy acres. We are almost at a loss to find words to describe the splendid new baths and pump-room, which have been completed this week. They are indeed pronounced the finest in Europe, and are fitted up with every modern appliance and convenience, including shower, vapour, douche, inhalation, and all kinds of local baths. Major Davis, F.S.A., of Bath, was the architect, and the Corporation of Bath authorized him to make a tour of all the principal baths in Europe some two years ago, before their own magnificent baths were erected ; so that the proprietors at Woodhall Spa have been most fortunate in obtaining the wide range experience of one of the leading specialists of the day. In the pump-room accommodation is provided for a first-class orchestral band, which during next season will play at stated intervals, when not required to play in the newly-erected band-stand outside the pump-room or new baths, the stand being almost a reproduction of the celebrated Kiosque in the South Kensington Gardens. Fine wide roads have been made upon the building estate, flanked on either side by trees. Several new villas have been erected, all of which are inhabited ; and thirty new shops will be completed in the course of the next few months, the whole of which, we believe, are either let already, or are in the course of being let. We understand that Messrs. Robey and Co., of Lincoln, are putting down new machinery for the elevation of the water, which, when completed, will deliver about 20,000 gallons a day ; and new tanks have also been constructed to hold some 60,000 gallons of water. An entirely new wing has been built to the hotel, which will be opened before the commencement of the season. The hotel is now leased to Mr. Roberts, of St. James' Hall, Piccadilly, whose catering gave such universal satisfaction during the past season. We understand that contracts have been signed for the erection of about twenty more villas, so that a still larger number of visitors will find accommodation. Plans of a new hospital have been prepared by Mr. Wheeler, of Boston, and in addition to the valuable site given by the present proprietors, subscriptions to the extent of £1,000 have been raised towards the carrying out of this most desirable object. We believe we are correct in stating that as soon as another £500 is forthcoming the proprietors intend to start the new building forthwith, as it is their earnest desire that both rich and poor should avail themselves of the benefits of this extraordinary Lincolnshire Spa. Remarkable as the success of last season proved,—for numbers of people were unable to gain any accommodation in the place,—we predict a still more brilliant season in the coming year. We trust that the Great Northern Railway Company will help the present proprietors of the Spa to the utmost of their ability, for at present nothing can be worse than the railway accommodation, both as regards the unpardonable delays at Kirkstead station and the station arrangements at Woodhall Spa itself. We cannot but wish the present proprietors all the success they so richly deserve, for when we think that Lincolnshire possesses an excellent water for the cure of gout, rheumatism and various other diseases, every credit is due to them for rescuing the Spa from comparative oblivion and making it more widely known, and, by their enterprise and energy, placing, within the reach of all, the benefits that are to be derived from the baths and water at Woodhall Spa.

WHITE LEAD MANUFACTURE.

BY A. W. WALLACE, M.D.

THROUGH the courtesy of Messrs. Fergusson and Co., we have had an opportunity of going over their White Lead and Paint Works at Mary Hill, Glasgow. The works are of recent erection and have abundant open space. The preliminary processes consist in removing the antimony and tin from the lead by melting it in quantities of twenty tons at a time, and skimming off the film which is formed, and which consists chiefly of the more easily oxidisable antimony and tin. The lead is run into ingots out of this furnace and is then placed in a succession of melting-pots, each holding about ten tons. After being melted it is kept stirred while cooling so as to allow the lead to crystalize. These crystals are removed from the rest of the lead; two thirds being taken away, and a third left behind. It is found that the silver which is mixed with the lead remains in the latter portion. The process is repeated till an alloy of over 400 ounces of silver to the ton of lead is obtained. The silver is then separated by cupellation. The pure lead is cast into plates about a foot long, and four inches wide, for the purpose of being converted into white lead. The following is the process:—A layer of spent tan is laid on the floor of a room twenty feet by twelve feet in area, and sixteen feet high; on this are placed rows of earthenware pots of two sizes, the rows of each size being alternate. These pots are all filled with dilute acetic acid. A plate of lead is folded up and placed in each of the larger pots, and over all the pots is placed a layer of the sheets of lead placed edgeways. Boards are laid for the workers to walk upon while arranging the lead over the pots. Over the lead is placed a layer of spent tan. On it rows of pots and a layer of lead, and so on, tan pots and lead in succession, till the room is filled. Chemical action takes place; some heat is generated, and at the end of three months the lead is all converted into carbonate. The room is then opened from the top, the plates of carbonate taken out, and crushed between rollers along with water. The bits of lead which have not been converted into carbonate are picked out, and the magma of white lead and water runs down into a settling tank. It is next put into bowls, and placed in a drying oven. At the end of a week it is dry. The bowls are then removed on an endless band, and hoisted to an upper storey, where the grinding and mixing with oil begins. The first process is to throw it into a copper in which a mixer is working. Some dust is given off when it is thrown in, but this is carried off by a fan working overhead. It then passes through rollers, by which it is incorporated with the oil, and is then either packed as white lead, or mixed with other colours for the market.

Almost all the work in making the white lead is done by young women. There are over thirty of them employed. The following are the precautions employed:—Each woman wears a linen overall while at work, which is washed every day on the premises. They come to work at half-past six; a breakfast of porridge is provided for them at nine o'clock by the firm, the workers providing their own milk. Their work is finished at two, and they have generally one day of the week free. Most of the girls are bare-footed—a common Scotch custom—and they are required to wash their hands and feet, and brush their teeth in the lavatory before breakfast, and before leaving the works. Once a week they have a hot bath, and a dose of Epsom salts and sulphuric acid. They wear respirators if engaged in any work producing dust. The most

dangerous operation is emptying the drying stoves, but this only occurs once a week, and the same girls are not employed twice in succession, and are removed in rotation to healthy departments. The result of this care is most satisfactory. The girls all look healthy, and many of them are rosy, in fact their appearance is very much above that of average factory hands. We saw women who had been from eight to fourteen years in the works who were perfectly healthy. The manager, to whose courtesy we are indebted for this interesting information, mentioned a singular fact, that some constitutions seem much more susceptible to the action of lead than others. Persons so predisposed became affected in a few weeks. When this happens, they are employed in another department till they get well, and then they are dismissed as unfit for the occupation. A small quantity of arsenical paint is also manufactured. Formerly the workmen suffered from eczema, but now the arsenical solution is boiled under a ventilator, and is stirred by a mechanical contrivance which admits of the workman operating at a safe distance from the fumes. The result is that skin affections have disappeared. We understand that the Government Inspector considers this the best arranged lead works in the United Kingdom. The proprietors have conclusively shewn that it is possible by attention to sanitary laws, and the employment of a manager who has the welfare of the employees at heart, to make a very dangerous occupation considerably more healthy than ordinary manufacture conducted in neglect of sanitation, and the grand lesson of it is that more real success will attend the scientific and moral education of employers and managers, than the multiply of legal enactments. All factories are under Government inspection, but enlightened and conscientious employers have done more for a dangerous occupation than Government inspection has been able to do with ordinary ones where sense and conscience are wanting in the owners. We by no means, however, intend to imply that Government inspection should be relaxed. Law is made for the lawless, and we believe there are lead works which are conducted with such reckless neglect of the welfare of the employees, that the proper course would be to indict the owners for manslaughter whenever a death from lead-poisoning takes place.

MONTHLY REPORT ON NEW PREPARATIONS,
FOODS, DRUGS, INVENTIONS, ETC.

Bingley's Sugar-free Ginger Ale.—There are many people who find that sugar produces acidity, and of course diabetics must avoid it in every form. Saccharine has been welcomed as a substitute for sugar, and Messrs. J. Bingley, of Northampton, have already adopted it in the manufacture of ginger ale, and with very great success. A sample of their manufacture has been submitted to us. We let some friends taste it without telling them how it was flavoured. They declared it to be the best they ever tasted. It is certainly excellent. We have seen it stated that the taste of saccharine persists in the mouth for some hours after being taken. This does not occur at all events as a result of drinking this ginger ale. The taste cannot be distinguished from sugar either at the time or afterwards. Messrs. Bingley prepare ginger ale of four different grades of sweetness. The lowest is half the sweetness of the sweetest, and the other two divide the interval, so that provision is made for a variety of taste. There are wonderful differences in quality, even in such an apparently simple a beverage as "ginger-pop." Those who buy Bingley's will not be disappointed in the article.

Clinical Cases.

ROYAL ALBERT EDWARD INFIRMARY, WIGAN.

Under the care of Mr. William Berry.

CASE I.—OVARIAN TUMOUR—OPERATION—RECOVERY.

By A. B. LIPTRON, M.R.C.S. ENG., L.R.C.P. EDIN.,

JUNIOR HOUSE SURGEON.

E. F., aged 38 years, admitted November 19th, 1884.

Family History.—Patient has had eight brothers and two sisters, of whom six brothers are dead from causes unknown, and one sister from cancer.

Previous History.—Has been married nineteen years. Never had any children—four miscarriages, all about the third month; the first six months after marriage, the second four months after, and the last about twelve years ago. Has always menstruated regularly every three weeks, but latterly has not seen so much. Says she first noticed a swelling above the pubes two and a half years ago. This was not more on the one side than the other. Her attention was called to this by a difficulty in micturition; since then she has been troubled with this at frequent intervals. Some time after, vomiting came on periodically every three weeks, and lasted a whole night. Never had much pain. Bowels constipated. Had to take purgatives regularly.

Present Condition.—Seems a fairly healthy woman—rather pale, but well nourished. Heart and lungs normal. Digestion good. Abdomen swollen. Girth at umbilicus thirty-eight inches. Shape typical of ovarian cyst; bulging anteriorly, not laterally; resonant in flank; dulness anteriorly. Contour somewhat irregular, with indefinite fluctuation. Thrill not communicated through whole mass, but only through portions. *Per vaginam*:—Uterus markedly antverted and fixed to some extent, cervix short, os nearly obliterated and very high. Uterus seems larger than usual. Sound cannot be passed on account of displacement and smallness of os. Bimanually uterus seems to be slightly attached to the tumour. On puncture of tumour with a subcutaneous syringe a clear viscid fluid was obtained, which was not examined under microscope. On a puncture being made next day a little external to the previous one, a dark-red gelatinous fluid was obtained, which, under the microscope, showed a large number of granules, "ovarian cells," as well as leucocytes, red blood corpuscles, and a number of large compound granular cells. Urine clear; sp. gr. 1032. No albumen; no sugar.

November 27th. Operation performed, few adhesions being met with. Pedicle was ligatured with silk and returned into the abdomen, and a glass drainage tube was inserted. Morphia suppository.

November 28th. Temp. 98.4°; evening, 99°. Dressing comfortable. Urine drawn off every six hours.

December 1st. Temp. normal—normal up to to-day. Fluid slightly bloody, drawn off every morning, and patient made comfortable. Temp. 100°; night, 103°. About three ounces of blood removed with syringe.

December 2nd. Patient comfortable. Temp., morning, 101°; evening, 103°.

December 3rd. Temp., morning, 101.2°; evening, 103°. About two ounces of fluid removed.

December 4th. Temp., morning, 101°; evening, 103°. Wound looks swollen and somewhat brawny between the stitches. Patient seems well.

December 5th. Temp., morning, 100°; evening, 102°.

About four ounces of fluid removed. Wound seems inclined to suppurate on stitch removed.

December 7th. Wound looks better, but still pus oozed out on pressure. Temp. 99°; evening, 100°. She progressed and wound slowly healed. It was evident that the peritoneum was closed excepting where drainage tube was inserted, and that there was suppuration between the muscles of the abdomen. Pus was pressed out every day. Iodoform powder dusted over. She gradually recovered, and was discharged cured on March 9th, 1885.

CASE II.—OVARIAN TUMOUR—SUPPURATION—INFLAMMATORY MISCHIEF FOLLOWING INTRODUCTION OF ASPIRATING NEEDLE—DEATH—AUTOPSY.

By J. BUCHANAN, M.B., C.M. GLAS.

SENIOR HOUSE SURGEON.

E. C., an out-patient, aged fifty-four, married, was first seen in December, 1884, complaining of gastric symptoms, constipation, pain in the back, and frequent micturition. She was relieved for a time, and ceased to attend the out-patient department. In April, 1885, she states that the last few months she has increased very much in size, and has a return of her old symptoms. She ceased to menstruate at the age of forty-seven, and has had a large family. Family history cannot be obtained. She herself has always been strong, and has had good health. Admitted as an in-patient on May 2nd, 1885.

Present Condition.—Abdomen much distended, principally on right side. Two distinct lobes or parts of same tumour could be made out. The one to the right the larger and more prominent of the two, with a sulcus running across the abdomen in an oblique direction under the umbilicus. Percussion over tumour dull, but resonant in flanks. *Per vaginam*:—Uterus anteflexed and somewhat flexed. Sound passes in three inches; behind and to the left some hard immovable nodules could be felt. No discharge at present from the vagina, but patient states that she has had some discharge every two or three weeks for the last three or four months. Urine contained a small quantity of albumen. On the 15th May she measured, over umbilicus, thirty-five inches. She vomits a good deal, and complains of pains in the back and loins. She was treated with stomachics and rest for some days, and put on a bland diet. A consultation was held, and as there was some doubt about the tumour, owing to its firmness, a small aspirating needle was introduced, and the syringe applied, but no fluid was obtained.

May 17th. She became severely ill. Pain in umbilical region very great. Temp. 102.2°; pulse 130. Girth thirty-nine inches. Sedatives were given, and also hypodermic injections to relieve pain.

May 18th. A good deal of sickness. Temp. 102.4°. Bismuth mixture ordered, and hypodermic injections.

May 19th. Patient a little relieved. Tongue dry, brown, and red at the edges. She is at times semi-delirious.

May 20th. She is a little better and more conscious. Still a good deal of pain, and much tenderness on pressure. Treatment continued.

May 24th. All the symptoms recurred with increased severity. Temp. 103.4°. She gradually got worse, and sank on May 26th.

Post-mortem examination was limited to examining the abdomen thirty-six hours after death. On opening the wall of the abdomen a large firm multilocular cyst was found growing from the left ovary. One of the small cysts was suppurating, and at least ten ounces of pus

escaped. There was very little evidence of any peritonitis, but it was quite evident that the suppuration had caused the pain and exhaustion.

Remarks by Mr. Berry.—In Case I. we had the peritoneum very soon united, and after its closure some suppuration in the sheath of the rectus muscle. Beyond this there was nothing special. In Case II., however, it was evident that after aspirating we should have performed abdominal section. Even if we had not done so then, it would have been well after the severe pain set in; but owing to there being a doubt as to the nature of the tumour it was unfortunately omitted. It was, however, very evident that if the abdomen had been opened the tumour could have been easily removed, and probably we should have had a successful ovariectomy.

Reviews.

Home Education, or Irish versus English Grammar Schools for Irish Boys. By MAURICE C. HIME, M.A., LL.D. London: Simpkin, Marshall & Co. Dublin: Sullivan Brothers.

A WRITER in the *Quarterly Review*, 1845, vol. 76, page 355, in a review of George Petrie's work, "The Round Towers of Ireland," tells us that there "was a time when Ireland was the light of the world, and that while knowledge, philosophy, and art were dying away in other countries, the light was kept burning there, and then spread over the greater part of Europe. Saxon kings, among them an Alfred, came to be educated in Ireland." Learning has, we believe, ever been esteemed in Ireland, and we are pleased to think at the present day the Irish schools keep up the national traditions, and that boys can be as well educated there as in England. We are already endorsing the opinion of Dr. Hime, who has written this book to check the exodus of Irish boys to English schools, and who, after a large experience as head master of Foyle College, Londonderry, is well qualified to treat on a subject of this nature. Though not a nationalist, he protests against the fashion of sending boys to English schools, so that they may acquire an English accent, etc.; and he proves conclusively that the peculiarity which distinguishes the Irish accent is not a bar to fame and fortune. Hundreds of Irish churchmen, dignitaries, statesmen, lawyers, doctors, artists, soldiers, scholars, and the rest, educated exclusively in Ireland, have achieved fame, even though they possessed the national peculiarity. Dr. Hime shows that 90.4 per cent. of distinguished living Irishmen were educated exclusively in Ireland; he gives the names and positions of a large number of them, and he draws from this the conclusion that as it has been possible for these men to win high positions in so many varied callings after home education, so boys of the present day need not fear that home education will be prejudicial to their advancement in after life. It is an economic question seriously affecting Ireland, if it be true that 1500 boys annually cross over to English Schools, for assuming that each boy costs £100 we have an aggregate sum of £150,000 lost to Irish schools. If as good an education can be obtained in Ireland as can be done in England, and at as reasonable a price, we cannot but regard it as foolish on the part of Irish parents to send their children away for the sake of fashion. Dr. Hime very eloquently concludes: "If one's son becomes as successful a politician as Lord Ashbourne, or Sir Charles Russell, Q.C., M.P.; as able a lawyer as the Right Hon. W. Gibson, Q.C., M.P.;

Hugh Holmes, Q.C., M.P.; or Mr. Digby Seymour, Q.C.; as brave and accomplished a soldier as Lord Wolseley; as deeply read a theologian as Dr. Gwynn, or Dr. Salmon; as lucid and eloquent a preacher as the Bishop of Peterborough, or Dr. Forrest, or Dr. Littledale; as wise and astute a judge as the Master of the Rolls, Chief Baron Palles, Sir J. C. Matthew, or Lord Justice Fitzgibbon; as profound a mathematician as Sir Andrew Hart, Professor Burnside, Professor Casey, Dr. Salmon, Mrs. Williamson, or the Provost; as sound and tasteful a classic as Professor Tyrrell, Professor Crossley, or Mr. Bury; as respected a philologist politico-economist as Dr. Ingram; as thoughtful and learned a metaphysician as Professor Maguire, or Mr. Abbott; as subtle a logician as Mr. Monck; as much imbued with the true spirit of poetry as Professor Armstrong; as versed in English literature as Professor Dowden; as charming a musician as Dr. Villiers Stanford, or Sir Robert Stewart; as admirable a painter as Sir Frederick Burton, or Sir Thomas Jones; as estimable a statesman as Lord Monck; as judicious a law lord as Lord Fitzgerald; as brilliant a physicist as Professor Tyndall; as eminent an analyst as Sir Charles Cameron; as great a physician as Dr. Quain; as skilful a surgeon as Sir William MacCormac, Sir George Porter, or Sir William Stokes; as prosperous and benevolent a merchant as Sir Edward Cecil Guinness; as gifted and spirited a war correspondent as Dr. W. H. Russell; as versatile a dramatist as Mr. W. G. Wills; as famous a financier as Sir Robert Hart; as expert and original a geologist as Professor Hull; as world-renowned a telescope optician as the talented and ingenious Mr. Grubb; as experienced and authoritative an engineer as Professor Crawford, Mr. Manning, Mr. Barton, or Mr. James Price; as capable and enlightened as Mr. Drew; as courageous and useful a civil servant as Sir Robert Montgomery; if one's son become as distinguished as any of these, and they were all educated exclusively in Ireland, then assuredly his parents may well, and they probably will, regard with perfect equanimity whatever manners or accent, be they ever so "Irish," he may happen to have."

Dr. Hime may be accused of being too severe on English schools, but he is supported by Englishmen. The *Educational Times*, February 1st, says in reference to the work, "Cræsus Minor."

"There can be no doubt, as Mr. Pember shows in every chapter, that the ordinary methods of education are wasteful and inefficient, and that the enormous sums spent by many parents yield no adequate return: boys become extravagant, conceited and exclusive, with no high aim in life, with a contempt for honest toil, and very little sympathy with the poor. Of course, as is pointed out, much of the indictment must be laid against the parents, who infuse their own spirit into the children, but a great deal is also due to the pernicious atmosphere of many preparatory schools. Summing up the bad results of much of our so-called education, Mr. Pember says, like a Ruskinian censor, 'As the workman stands, pipe in mouth, opposite the Criterion or the gilded buffets in London, and sees the young men, who ought to be the guardians of the State, who are called the aristocracy, who have been for twenty-one years the recipients of a costly education, impotent to govern their own passions, vulgar, reckless, extravagant—do you wonder if he asks, 'To what purpose was this waste!' and, having asked, adds, 'How long?'"

Syphilis. By JONATHAN HUTCHINSON, F.R.S. (illustrated). pp. 532. London: Cassell & Co., Limited.

FOR years Mr. Hutchinson has been writing on syphilis, showing the many sided nature of his medical accomplishments, and Messrs. Cassell were fortunate in securing his pen to write a manual suitable for practitioners and students of medicine. In these pages we have, if not all that is text of his writings, at least his matured views on the many important questions that arise in connection with syphilis, and as he has given us facts, notes from practice,

to illustrate his views, we are placed in the most favourable condition to estimate the value of his conclusions. The work is divided into two parts, the first dealing with general statements, as primary symptoms, secondary symptoms, intermediate symptoms, tertiary symptoms, treatment of syphilis in general, on congenital syphilis, and the laws of inheritances. The second part consists of clinical commentaries and illustrative cases. The phenomena of syphilis, alluding to Mr. Hutchinson, result from the introduction into the system of a specific poison, and this poison, in all probability, consists of particulate (or organic elements). This is a framed definition, but it is more positively stated that the disease depends on a living and specific microbe, and this microbe may be introduced on the lips, fingers, etc., as well as by coitus. The treatment of chancres is of importance, and here Mr. Hutchinson lays down a positive dictum, "If a patient who has never suffered from syphilis before, and who can give his dates correctly, comes under observation at any period within a fortnight of contagion, with a single sore, it will certainly be wise to destroy it utterly." For this purpose he recommends fuming nitric acid or the cauter, For many sores he advises free washing and the application of iodoform, as one drachm of iodoform to one ounce of vaseline in non-indurated sores, this being especially effective. "It may be asserted," he says, "that the introduction of iodoform has rendered the treatment of non-indurated sores a very easy matter. The same remark applies to the suppurating stage of true chancre." A very optimistic view. On the general treatment of syphilis our author is a believer in mercury. "In the early stages of syphilis the iodide of potassium is comparatively powerless, and mercury should be used. Thus the induration of a primary sore will resist the influence of the former, but melts away when mercury is given. So also of the secondary phenomena, all of which, excepting perhaps sore throats and sores in the mouth, are best treated by mercury." The various methods of giving mercury are described, the writer praising the use of the ordinary grey powder. One of the most important questions, and one frequently asked, is, "When may a patient marry who has had an indurated chancre?" We believe that Mr. Hutchinson's limit may be practically accepted—viz., two years, that is to say, if the patient has undergone a carefully adjusted course of treatment of not less than six months. The second part of the book is, in our opinion, the most interesting; put in the form of commentaries, and with details of cases that have come under the author's notice, it is sure to be instructive. He here runs over the most divers questions, falling back on his own experiences for answers, and though there is no method in his arrangement of the material in this part of the book, this is counterbalanced by the wealth and illustrations afforded by clinical cases, and by the very conversational style in which the questions are put. Syphilis forms such an important and common part of practice, that the general practitioner should be well posted up on it. This work of Mr. Hutchinson is admirably suited to the needs of general practice.

BETA.

On Hemorrhages and False Membranes within the Cerebral Subdural Space, occurring in the Insane (including the so-called Pachymeningitis). By JOSEPH WIGLESWORTH, M.D. Lond. An Essay to which the Prize of the Medico-Psychological Association has been awarded.

IN our present imperfect knowledge of the pathology of diseased mental states, we welcome any contribution that throws light on the anatomical changes that underlie or

accompany them. The existence of false membranes on the inner surface of the dura mater in cases of insanity has long been recognised as of frequent occurrence, and has generally been ascribed to chronic inflammation. Writers are, however, not agreed as to the origin of the appearances found, and Dr. Wilesworth has undertaken a series of observations in regard to it, the result of which is contained in the present pamphlet. Out of 400 *post-mortems* on cases of insanity, either false membrane or blood was present in forty-two, the two conditions occurred in the same class of cases, and passed by insensible gradations into each other. Patients that during life had symptoms of cerebral hæmorrhage and recovered, were found, after death some months later, to present the membrane usually ascribed to pachymeningitis. From these considerations, as well as from the absence of marked signs of inflammation, and the frequent limitation of the affection to one side, Dr. Wilesworth concludes that the appearances attributed to pachymeningitis are in reality due to previous hæmorrhage and are not the result of inflammation at all. The hæmorrhage he considers as being to a great extent compensatory to the shrinking of the convolutions, and brought about by loss of support of the vessels of the pia mater and the occurrence of local congestion of the meninges. The former factor seems likely to operate in general paralysis, in which the condition under consideration is most frequently found, but we cannot agree with the writer in supposing that small effusions of blood may take place by diapedesis without any breach of the continuity of the vessels. This however does not affect the main argument, and we congratulate the writer on having made a solid contribution to our stock of pathological knowledge, founded on an extensive experience and worked out by a careful induction.

T. R. BRADSHAW, M.D.

Short Notices.

Ophthalmic Surgery. By ROBERT BRUDENELL CARTER, F.R.C.S., and WILLIAM ADAMS FROST, F.R.C.S., with ninety-one engravings. London: Cassell & Co.

Books published under a joint authorship are not usually satisfactory. In this book we have, however, chapters written by the two authors and signed by their initials, so that an individual responsibility is assumed, and we are assured that both authors are in general agreement on all the portions of the work. Mr. Brudenell Carter has contributed the articles on the anatomy and physiology of the eye, the examination of the eye, affections of the cornea, and the anterior zone of the sclera, diseases of the iris, the lenticular system, glaucoma, optic disc, retina, choroid, and posterior half of sclera, amblyopia, and amaurosis. Mr. Frost treats of affections of the eyelids, lachrymal apparatus and conjunctiva, affections of the vitreous, color vision and its defects, injuries, errors of refraction, affections of the ocular muscles, and affections of the orbit. It is only possible in 540 pages to present a very concise account on the present state of ophthalmic surgery, and the authors are to be congratulated on the way they have presented it, and on placing at the disposal of the practitioner a useful work on a branch of practice too much neglected. Amongst the chapters, those on the examination of the eye, on errors of refraction, and colour, vision will be found most serviceable. There is really too much haphazard prescriptions of spectacles, and much harm done by cheap and unsuitable glasses. We can confidently recommend the book as an excellent addition to the series of manuals now in course of publication by Messrs. Cassell & Co.

L. R.

The Provincial Medical Journal,

MARCH, 1888.

THAT to do any good, medicine must be "mixed with brains," is a fact that needs to be burnt into the minds of not a few, especially of working men. When it is decided to accept the lowest tender for any article of commerce, the analyst can be appealed to in order to secure that the article delivered is "up to sample;" but no provident dispensary can secure a sample of its physician's skill whereby to test the quality of the service he afterwards supplies, nor can the most subtle analysis determine whether the best quality of thought is being given to the case in hand. The patient is helpless in the hands of his medical adviser. He has absolutely no security but the conscientiousness of the physician whether he shall be supplied with the reality of sound advice, or the sham of learned talk. By a fair amount of dexterous assumption, and some skilful "prophesying after the event," he can always shew that patients who die do so because they must, and those who get well owe their lives to the physician's skill. Working men may think that they have "done the doctor" by the low terms on which they get him to work, but it is in the same sense in which the man said "he had done the insurance company" because he was dying of pneumonia. Let us see now whether the provident dispensary system has a very sound foundation to rest on. Take two hundred families in a manufacturing town. This will represent a thousand people. There will be thirty-five to forty births among them; twenty-five to thirty deaths if they belong to the artisan class. There are about twenty-five cases of illness for every death, so that there will be at least 3,000 cases requiring advice during the year. The average duration of illness has been found to be a fortnight. If but three visits at an average are made to each case, that is 9,000 per annum, or 25 per day; but as illness is very unequally distributed over the year, in a sickly season the visits will run up to fifty or sixty per day. This with thirty or forty midwifery cases is pretty good work for any man. Let us see now how it stands as to pay. £400 a year is the least for which it can be expected such work would be well done, and medicines supplied. Allow £40 to be got in fees for midwifery, then £360 must be distributed over 1000 people; that is, each must pay about seven shillings per annum. Will the working classes pay this sum? We fear not, for though not very much, certainly, if all were earning, when a working man has "ten small children" with himself and his wife, the annual rate is £4 4s.; a very serious matter indeed for a man with small wages. There is another serious difficulty. A man in the prime of life is liable to less than a week's illness in the year; one between fifty-five and sixty to over three weeks; young children to quite as much. Viewed from a commercial standpoint, the vigorous man will decidedly object to pay the same rate as the man more liable to sickness, and yet he is the best able to afford it. These are objections which appear to us to make it impos-

sible ever to establish provident dispensaries on a sound commercial basis, just to the medical attendant, as well as to the working classes. If the rates are such as to secure proper medical advice, they will be beyond the reach of the very class for whose benefit they are intended. There are two ways in which these difficulties may be overcome. First by the individual practitioner; next by organisation. The medical man should keep his fees for single visits and short attendances well up, and then, as an act of kindness, and not as a right to be demanded, he can lessen the charge per visit where the attendance is long and the circumstances of the family straitened. Medical men should agree to a tariff of first fees—that amount or none. But no conscientious physician could bind himself in every case to exact his pound of flesh during a long attendance. Next as to co-operation. The only sound principle on which this can be done is that the strong shall help the weak. This principle is not a commercial one. But there are more things in heaven, and in earth as well, that are not dreamed of in some men's philosophy. Altruism is not dead yet. The love of one's neighbour is still a survival. That the best helpers of the very poor are found among those just a step raised above them, in straitness, is a great fact which political economists have never realized. A dispensary supported by the pence and farthings of labouring men, in the management of which they share, and which has for its object the relief of sickness, because the sufferer is a brother in need, and not because he is a subscriber, is the true solution of the question. In such a case there is no sacrifice of dignity in the physicians and surgeons accepting a lower rate of remuneration than under other circumstances they would take. But the emolument should be fixed, and no room given for "putting in a tender." Further, every case seeking relief should be subjected to strict scrutiny, yet with that delicacy which will not interfere with the self-respect of the deserving recipient. It is truly said that the present indiscriminate system of medical charity is demoralizing the working classes. The only way to mend matters is to associate the working classes as intelligent helpers in the relief of real distress. We shall return to the subject soon, and prove from facts that our contention is no mere theory, and in the meantime we repeat our protest against the provident dispensary system as false in principle, and mischievous alike to those who give and those who take.

THOSE who may have seen our book on "Rabies or Hydrophobia," may have been struck by the conclusions we arrived at in 1877 on the pathology of hydrophobia. We then said: "We may fearlessly propound the following provisional conclusions:—

1. That the phenomena of rabies, as evinced by morbid anatomy, depend on structural alterations in the medulla, oblongata, and spinal cord, *influenced by a specific virus, the modus operandi of which is yet involved in obscurity.*"

This paragraph stands as true to-day as when it was

written. The subsequent researches of Dr. DUBOUE, of Pau (1879), and of M. PASTEUR have confirmed the accuracy of our provisional conclusions so far as the location of the virus in the medulla and spinal cord, but, unfortunately, the second part of our conclusions yet remains *in statu quo*, and the nature and mode of action of the virus are not known. In all we have written on M. PASTEUR's work, we recognised how far he had gone on new lines, and what we owe to him; and in our pamphlet we clearly pointed this out. We drew, however, the line, differentiating between his experiments on animals and his experiments on men. The application, under other conditions and other methods, of a system which succeeded with one class of animals, was not logical. We need not go over the old ground. Briefly stated, analogy is not identity. We now allude to the subject again to draw attention to the observations of Dr. KLEIN, which so singularly coincide with all we have written, and which, coming from an independent source, and from one well justified to speak, will have more weight than anything we could say. At a recent meeting of the Epidemiological Society, Dr. KLEIN read a paper on "Some of the Infectious Diseases common to Man and the Lower Animals."

In the course of his address Dr. KLEIN said: "The subject of hydrophobia has, by the teaching of PASTEUR, received important additions. His long and arduous labours, carried on for several years, and confirmed by many independent workers, have established, beyond doubt, the following facts:

(a) The fresh brain and cord of an animal or man affected with the disease contain the virus of rabies in an active form.

(b) The intracranial injection of such virus is followed by the disease with certainty after an incubation varying in duration in the different species.

(c) Drying the cord or brain diminishes its virulence; this shows itself by a delayed incubation, and by a modification of the character of the disease, inasmuch as it gives place to "paralytic" or "dumb rabies." If the process of drying is carried sufficiently far, but not too far, no rabic disease, but an immunity against rabies is produced by inoculation with the fresh material.

(d) The inoculation with virulent matter (natural or experimental), simultaneously with, or followed by that of attenuated virus of the proper degree, is not followed by the outbreak of the disease, hence it is possible to overcome the action of the virulent poison.

(e) The disease is also, but unreliably, produced by subcutaneous inoculation of cord and brain matter; as also, but still more unreliably, by the saliva.

From these facts PASTEUR has drawn certain conclusions, which, if established, would give a means, not only to stamp out rabies amongst dogs, but also prevent rabies in man; for it must be obvious that by subjecting all dogs to inoculation with attenuated virus, no rabies dangerous to man could develop in them; and further, by inoculating human beings bitten by a rabid animal with attenuated virus, the disease would be prevented. These conclusions, though

fully justified, cannot however be considered as fully established. Their applications to the human subject are far from understood. (a) *In the first place, the method of inoculation, as practised by M. PASTEUR on the human subject, i.e. subcutaneous inoculation—intracranial injection not having been, and is for obvious reasons not likely to be, employed—is not sure of success, if as a basis for such a proceeding the knowledge gained by animal experiments is to be relied upon.* For in the series of experiments made by Von FRISCH in Vienna, and by Mr. DOWDESWELL at the Brown Institution, it is clear that the results in the rabbit or the dog are altogether dissimilar; for whereas in the latter species this method did lead to protective inoculation in some animals, in the first species—i.e., the rabbit—it produced true rabies. M. PASTEUR's *protective inoculation in man also led, in a certain percentage of cases, to fatal results.*

(b) Secondly, the question of the degree of attenuation the cord undergoes by drying, although established for the rabbit's cord, is not established as far as its application to the human subject is concerned. PASTEUR's and others' method of using the cord of rabid rabbits in successive degrees of attenuation—starting with the use of a higher, and proceeding to that of a lesser degree of attenuation, either slowly or rapidly (intensive treatment)—is tentative; and for this method no firm and clear basis is as yet available, since no one knows what is the minimum and what is the maximum degree of attenuation of rabbit's cord *quoad hominem*.

(b) *Another uncertain factor in the application to man of the protective inoculation is the fact that the incubation-period of rabies in man exhibits such a conspicuous difference in the different cases. As is well known, persons bitten by rabid dogs and seized with hydrophobia show a wide range of incubation-period. If, as PASTEUR assumes, from his animal experiments, a difference in incubation-period indicates a different degree of virulence of the rabic poison, then no assumed degree of attenuated virus could rationally be recommended for protective inoculation, since the duration of the incubation-period, in a given human case, is obviously a matter of conjecture.*

(d) But above all, *the intimate nature of the rabic virus being as yet not known, no definite and conclusive insight into its modus operandi is available.* Various observers have described organisms as being the cause of rabies, such as those described by FÖL; but there is really no definite proof forthcoming. Mr. DOWDESWELL has seen masses of micrococci in and around the central canal of the cord in a rabid dog, but has missed them in other cases. Quite recently a Russian observer described bacilli as the cause of rabies; but from his experiments it is quite clear that the microbe of rabies remains to be discovered. When this is done, and not until then, definite and clear proof will no doubt be obtained on some of the most essential points of the problem."

If we compare the general statements in our pamphlet with those above, it will be seen how close we are in agreement in our estimation of the method PASTEUR. Hydrophobia has

not yet been brought under control, but as we have so often said, "We hope we are on the high road to success, and by persevering we shall yet overcome it."

IN *Der Fortschritt*, Dr. Wyss has given a very able summary of some modern views on the treatment of phthisis. If we examine his data we shall be forced to the conclusion that we are still groping in the dark, and that the therapeutics of to-day are not much more advanced than they were before the bacillus tuberculosis was discovered. The treatment of phthisis, says Dr. Wyss, is viewed from two different points. In the first the pathogenic agent, the bacillus, is attacked directly; in the second the system is strengthened, so as to resist the bacillus. The two methods are employed simultaneously. It is convenient to consider the methods separately.

1. *Bactericides*.—(a) Anti-tuberculosis vaccination, after the method of attenuation by PASTEUR, has been tried by CAVAGNI, but his experiments have not yet broken from the limits of the laboratory; but as NAUNYN, of Leipzig, observes, there is ground to hope that a true preventive vaccine will be found. VERNEUIL in 1886 proposed the establishment of a prize to encourage research in this direction.

(b) *Bacterio-therapia*.—An ingenious Italian suggested the inhalation of cultures of harmless bacteria, which would devour the destroying bacillus. Professor CANTANI was the promotor of this system. [An enterprising English practitioner took this up, and in a handbill submitted to us, we saw the grave announcement, that he was prepared, for a fee of £2 zs., to supply pure bacteria for inhalation. This system soon died.]

(c) *Anti-Bacterian Medication*.—The chemical substances which have the reputation of killing the bacilli, owe their prominence to clinical empiricism rather than to experimental research. They owe their inception to the antiseptic theory. In support of this system we find the names of METSCHNIKOFF, WYSSOKOWITCH, BRIGER, and others. BUCHNER, basing his method on this idea, suggested a powerful remedy.

1. *Arsenious Acid*.—The employment of arsenious acid dates back to Roman times. PLINY and DIOSCORIDES cured cases of phthisis by "sandrake," a substance compounded of sulphuret of arsenic; thrown on hot cinders, it gave off vapours, which the patients inhaled. In spite of the recommendations of SLEVOZT (Izod) arsenical preparations were rarely employed. It is to the celebrated clinician, TROUSSEAU, the merit of their re-introduction is due. TROUSSEAU found in "DIOSCORIDES" the following:—"We give arsenic internally to patients who have pus in the chest; mixed with honey, it renders the voice clear, and we give it to asthmatics, and for patients who have invertebrate cough it is respired." TROUSSEAU caused cigarettes to be made, each containing five to ten centigrammes of arsenate of soda, giving internally pilules made of two to five milligrammes of arsenious

acid. Relief was obtained in some of the most distressing symptoms. According to BINZ and SCHULZ, arsenious acid acts on the cellular protoplasm, which undergoes molecular transformation, more or less intense. Thus modified in its internal constitution, the cellule engages in a struggle with the bacterium; in place of allowing itself to be destroyed, it becomes the tomb of the vanquished enemy. BUCHNER has in Germany recommended this agent, though it has not met with general acceptance.

2. *Creasote*.—Discovered in 1832 by REIEBENBACH, creasote has been employed by numerous foreign observers, but it has not found much general support.

3. *Menthol*.—Drs. ALBERT and ROSENBERG, relying on the antiseptic properties of this stereoptine, have recommended it in phthisis, either in the form of inhalations, or pilules, or cachets. LAAGAARD gives the following formula:

Mentholi	2.0
Sacch. albi	
Gummi arabi	āā 1.0
Aquæ destill.....	qs.

ut. ft. pil No 20. Obdue gelatina. Each pill contains 0.10 menthol.

3. *Rectal Gaseous Injections*.—BERGEON's method has been much praised by some writers, but the accumulating evidence is not favourable to it. He proposed to bring the curative agent into direct contact with the microbes, without hurting the organism. This he proposed to do by gaseous injections by the rectum. BERGEON found that a mixture of carbonic acid and sulphureted hydrogen was tolerated in the rectum when these two gases were pure, and deprived of atmospheric air. The mineral waters of D'Eaux-Bonnes were used. The sulphureted hydrogen was the agent designed to kill the microbes. The climax of treatment, we believe, has been here reached; the absurdity has been emphasized by the suggestion made, half in fun and half in earnest, by an American contemporary, that phthisical patients should eat *beans*. Looking at the treatment of phthisis in modern times, we are reluctantly forced to the conclusion that we have not made any advance, and that we must fall back upon the general principles of treatment which have been clearly advocated by physicians who regarded consumption from its clinical side, and from the standpoint of observation and experience.

DR. E. M. BRILL, of New York, makes rather a sweeping charge against medical experts in the paper he read before the Section on Medical Jurisprudence at the 38th Annual Meeting of the American Medical Association. He rather insinuates that railway doctors look through railway spectacles, and that the expert called in by the persons suing the railway company also looks through spectacles coloured by the fee received from the side on which he is summoned. We think his picture overdrawn. He says: "Were all actuated by the desire that truth should prevail, and with no regard to the condition of their pockets, there would be in the great majority of litigations but one expressed opinion. How can a fact be anything else than a fact? and how can

the significance of a certain regular combination of signs or symptoms be considered in any other than their true significance?" He answers this question himself by the following case. He says: "There is a well-known case described by LEYDEN of spinal concussion caused by a railway accident, in which the patient's sufferings at the time were but trifling, and he not improving, and becoming unable to work, was mistaken for a simulator; and finally, after many years, severe symptoms appeared, and resulted in death." It is exactly this class of case which experience tells us frequently does arise. And here facts have to be interpreted by each one's individual experience, so that it is not so simple as it looks to pronounce an opinion even on the most apparent symptoms. The railway doctor would appear to be justified in view of trifling symptoms to say this man is a malingerer; whilst some expert having had a case where trifling symptoms subsequently ended in death, might justifiably appear in the witness-box to controvert the railway doctor's opinion. Who shall dare to say that either are influenced by unworthy motives in pronouncing even antagonistic views? There is nothing more certain than the uncertainty as to how railway accidents may terminate. We have known cases where the gravest injuries have been received, and on the nature of which there has been a perfect agreement between the medical officer for the company and the family medical attendant. Prognosis has been given with unanimity that the injuries must end in death, or permanent disablement. Re-compensation has been awarded even to the extent of £10,000. Simulation has been out of the question. Objective and subjective signs have been present to guide experienced physicians and surgeons, yet after some years the patients have been able to again take up the thread of their lives, and resume their occupations. Again, experience also tells us of cases like that recorded by LEYDEN, where injuries, seemingly simple, and treated as of trifling moment, have a few years after the accident, and after settlement, ended in paralysis and death. Spinal concussion is something more than a fashionable name; it is a many-sided symptom. One person may be injured in a railway accident, and throw off the effects thoroughly; whilst another through some inherent weakness may in a few years only show signs of the accident. Subjective symptoms may be of slight or of very great moment; the difficulty comes in the differentiation of the value of these symptoms. Expert testimony has to be guided by many factors, and it is only fair to assume that those who are called in either on the part of the railway or the patient, give their testimony honestly, and without a partisan bias. It is quite possible that in estimating the value of the subjective symptoms, an expert may in one case give an affirmative, and in another negative evidence, as his evidence is based on the sum of the conditions which may necessarily be alike in many cases of accident, in general features, though varying in one essential particular, which make all the difference in the opinion given. Cross-examination, as Dr. BRILL truly says, tests the ability and qualification of a witness, and in this cross-examination we

have the protection for the company sued, as well as for the plaintiff. Under it a weak case is as a rule exposed, because juries are not so dull as not to be able to estimate the value of evidence, and so appraise at its proper value evidence given for the sake of money. In England we have no trained experts except for cases of poisoning, where chemical skill comes in. In the general class of cases specialists, we presume, take their place, as they are to all intents and purposes experts. When specialists are called in, we believe they give their opinions honestly, even though opinions may differ. No two minds are alike. What are so ostensibly and so easily labeled facts, are not so easily to be agreed upon. We may take the case of the illness of the CROWN PRINCE. It is a fact that he has something the matter with his larynx; it is a fact that his larynx has been explored and examined, that there have been objective and subjective signs to guide his medical attendants, yet with such facts, what difference of opinion. One set of observers see in the objective and subjective signs "cancer;" the other give a different and more favourable opinion. Here there is no pecuniary object in view to bias the observers, simply the facts are interpreted in different ways. Thus it is in all cases of accidents, objective and subjective signs have their peculiar significance, not from the bias of the observer, but from the individuality of the observed, who sees in the symptoms a gravity or slowness, depending upon, may be, his antecedent experiences of other cases, or on particular views of pathology. We want a little more charity in our profession towards those who differ from us; it is easy to impute improper motives, against which no man is safe. Dr. BRILL includes in his sweeping indictment, lawyers, and even judges, so that we must not complain if he includes physicians as well. He writes as an impartial, and as a philosophical observer, but we very much fear that he has mistaken his charter; that he has, unconsciously, no doubt, himself been biased, as much as the experts he condemns, by a want of ability to differentiate on the value of evidence and facts.

Annotations.

"Forsan et hæc olim meminisse juvabit."

THE CLERICAL, MEDICAL, AND GENERAL LIFE ASSURANCE SOCIETY.

THE sixty-third annual general meeting of this Society was held at the close of the year 1887 at the Society's office, and the report is most satisfactory. As this Society has a number of medical men on its board of directors, we look upon it as if it were connected with the profession. The names of the medical directors command confidence—viz., Deputy Chairman: Sir William Bowman, M.D., F.R.S. Directors: Lionel Beale, M.B., F.R.S.; Sir Prescott Hewett, M.D., F.R.S.; Professor Humphry, M.D., F.R.S.; Sir William Jenner, M.D.; Sir James Paget, F.R.S.; Richard Douglas Powell, M.D.; William Overend Priestley, M.D. Prospectuses can be obtained from the Secretary, 15, St. James-square, London, S.W.

HOSPITAL REFORM.

At a meeting of the Great Northern Hospital, one of the governors, Dr. Burnes, brought forward the present method of dispensing charitable relief in the out patient department of our hospitals. Dr. Burnes in a circular thus expressed his views:—"Tradesmen and other persons, in a good position go down to the hospitals and get supplied with costly instruments at a small charge—nay, cases have occurred in which an out-patient in good circumstances, after obtaining a one month's supply of an emulsion and medicines for his child, on the plea that it was going away, actually went and sold it to a chemist a little way from the hospital. Thus the money, contributed by generous donors for the relief of necessitous persons, is diverted from its proper channel and those who are able and who would be glad to pay a small fee in order to obtain the skill of eminent medical men, are obliged to consort with the mass of out-door patients, and to receive relief gratuitously. How are these recognized and growing evils to be prevented? Several plans have been brought forward, and notably that of provident dispensaries, in connection with and affiliated to the various hospitals. I venture to submit a plan for the relief of this crying evil, which I think has none of the objections inherent in other solutions of the difficulty, and which, moreover cuts at the roots of the mischief. It would be necessary for the success of the plan that all the general hospitals in London should co-operate to bring about a reform, but as all alike suffer from the congested state of the out-patient's department this would present no insuperable obstacle. The plan is briefly as follows:—In each district of which a hospital forms a centre, an officer should be appointed, styled the Superintendent Almoner, with an office in or near the hospital. Here he would receive all applications for admission to the out-patient department and would make enquiries as to the circumstances of the applicants. He would be able to recommend them either free or on payment of a certain weekly fee, according to their means. Cases in the first place would have to be taken with an order, stamped by the Superintendent Almoner, to any one of the extra-mural officers, affiliated to the hospitals. These officers would be registered medical practitioners, of not less than three years' standing in the district, and a list of such officers would be kept in the office, so that the patients might select whom they pleased. The extra-mural officer would see the case, prescribe for it at once, and should he be satisfied that it was of an ordinary nature and required no special treatment, he would continue to undertake the case. Should he, however, think fit, he would at once endorse the order for admission to the out-door department of his hospital. The fees charged by the almoner would be payable to him, and he would account for the same to the committee. The extra-mural officer being granted a nominal sum per week (say 1s.—3s. 6d. for home visitation) for his treatment of the case while it remains in his hands. The Superintendent Almoner would report every case to the committee, with extra-mural officers's report annexed, if the

case remained in his hands. Of course it would be provided that such patients should attend at the hospital whenever required for examination, &c., and that the extra-mural officer should make a special report of every case which has been in his hands for more than three weeks. The Superintendent Almoner would be expected to make enquiries as to the case of each applicant, and to fix the fee to be paid per week (if any), in accordance with the result of his enquiries. Hence, his first order for medical relief would be only a temporary one, to be endorsed or cancelled as might be necessary. Thus the out-door department would be relieved of its congestion, the necessitous would still receive free relief, while those able to pay would be compelled to contribute to the cost of the charity. As for the financial part of the matter, there would be on the one hand the expenses of Superintendent Almoner and his office, and also the nominal payments made to the extra-mural officers to cover cost of medicine, &c., while on the other hand there would be the money received by the Superintendent Almoner in accordance with his decision.

THE BATHS OF KRANKENHEIL-TOLZ.

THE baths at Frankenheil in the Bavarian Oberland are deservedly attracting the notice of physicians, as the properties of the waters are becoming better known. Tolz is a small town of about 4,000 inhabitants, 670 m. above the sea, and is picturesquely situated on the borders of the Isar, and surrounded by mountain scenery of the most impressive character. The development of Frankenheil has been largely due to the enterprise of the late M. Karl Herder and Dr. Höefler, and under their influence the accommodation for visitors has been made most complete, the bathing arrangements particularly being developed. The season commences about the 15th of May, and terminates on the 15th of October. Those who desire a foreign resort away from the feverish life of some of our health resorts, will find at Frankenheil that repose so much needed, but not found where gaiety and fashion are the rage. There are excellent hotels, as the Badehaus, Kurhotel, Hotel Sedleman, Hotel Dreppold, Tollhaus, Pension Spenger, besides numerous other restaurants and chalets, which can be rented at a reasonable price. During the season an excellent band is engaged, and other attractions are provided. The climatic conditions of Frankenheil are most favourable. The pure mountain air, with plenty of sunlight, and usually a west wind, conduce to a rapid restoration of patients who require mountain air, and a tonic atmosphere. Apart altogether from the surroundings, Frankenheil possesses some very valuable springs, which have been used with very great effect in cases requiring an alterative treatment. The waters have been found of special value in some diseases of women. In the treatment of obstinate skin affections the Frankenheil soaps are invaluable. In a series of pamphlets issued under the title of "Europe Illustré" (Orell Fussli and Co.), there is an excellent account of Frankenheil and its waters,

THE CLIMATE OF OBAN, N.B.

THE year 1887, has maintained its character for dryness to the end. One of the most remarkable features displayed in the yearly returns for Oban is the high position maintained in regard to the purity of the atmosphere, as shown by the ozone register. "Experience has thoroughly established the fact that where the amount of ozone in the air is *constantly* high, there we almost invariably find a high degree of salubrity."—Burney Yeo. Undoubtedly, the low death-rate, and the general high standard of health enjoyed by residents in Oban, can be in great part explained by this fact. A reference to the following table, in which Oban is compared with other important and well-known towns, demonstrates very clearly the large advantage which Oban possesses in this factor as a health resort :—

QUARTERLY MEAN AMOUNT OF OZONE, REGISTERED OUT OF MAX.

	1886.	1887.	
CALCULATED AT	IV. Quar.	I. Quar.	II. Quar. III. Quar.
Guernsey	3.4	4.1	4.4
Torquay	4.4	3.9	3.7
R. Observ., Greenwich ...	2.3	2.5	2.9

(Signed) G. WOULE BREMAN, C.E.,
F.R. MET. SOC.

EDWIN BAILEY, F.R. MET. SOC.

The variation existing in the total of this column, and in that exhibited in the 4th quarter of the year, is accounted for in the fact that the above table is computed from the maximum rainfall registered at the high and low level observing stations. The quarterly total is arrived at by taking the high level rain register alone into consideration.

HE HAS THE COURAGE OF HIS OPINIONS.

IN the Report, 1887, of the Medical Officer of Health (Dr. Masterman) for Stourport, we find the following outspoken expressions of opinion :—

But, it may be said, as one death-rate, 20.00 per 1,600, is only that of the urban average, why should I speak of it as excessive. The answer of all competent men is—Because that average *is* excessive and wasteful. The normal and perfectly attainable rate is about 12 per 1,000, and the average age at death should be 55 years. Amongst the Society of Friends only about seven per cent. of their children die under the age of five years; in this parish more than fifty per cent. die before attaining that age. But the foregoing figures shew that amongst the poor, the very parish poor, the death-rate can, by moderate personal attention and the unsparing use of means which recent science has placed in the hands of educated medical man, be brought nearly as low as amongst people with every advantage of wealth and inherited healthfulness in their favour. The great difficulty which meets one in attempting the solution of this and cognate social problems is the personal element on the one hand and the stolid ignorance of the bulk of the people in all matters affecting public health on the other. It is easy to write an Annual Report dealing simply with results and the customary calculations of rates and averages; but the duty of a Medical Officer of Health goes far beyond that: Every question belonging to matters which affect the lives and well-being of the people is within his province, and he is bound to disregard all personal considerations in dealing with them. "The physician," Hippocrates tell us, "must not only be prepared to do what is right himself, but also to make the patient, the surroundings and the attendants co-operate," and this is the difficulty in dealing with the

lower and unreasoning classes. The very poor and hospital patients have, happily for themselves, very little choice in the matter, they are almost obliged to obey the orders given; and the higher and educated classes are too intelligent to disobey them, and so the results in both cases are generally satisfactory. But it is equally ludicrous and provoking to see how people assume the right of private judgment in questions on which they are utterly incapable of forming any rational opinion, and there can be no doubt but that this greatly increases their own and infant mortality by interference with or neglect of the treatment directed. Again, in general terms there can be nothing but commendation of the so-called "club." They are doing more to relieve the rates and teach the value of self-help than any organisation. But the system is reacting disastrously in the very direction where it is intended to be most useful: by neglect of the wage-limit in placing the poor and the well-paid artisan, and often the prosperous tradesman, on the same low level of contributions, it is making the medical appointments a test of professional degradation and keep up a class of practitioners of a very undesirable type, which, at no distant date, will alone consent to hold them. As it is, the medical journals teem with advertisements of unqualified assistants, of holders of single diplomas and third-class licenses, to cheaply take charge therein and—in plain terms—what else can be expected for the money! If the question were how to get something of definite value (but that, from the personal equation, it cannot be) at the lowest possible cost, the less paid the better. But only to get medical attendance of any kind and secure some slipshod death certificate to the avoidance of an inconvenient inquest, it is too much to pay even a penny a week for, since men can be found to undertake it for half the sum. *But even in these woeful times, it may be found possible to die too cheaply.*

MEDICAL MONOPOLY IN EDINBURGH.

THE *Scottish Leader*, of January 18th, has an excellent article "On Medical Monopoly in Edinburgh," which opens with the following statement:

It is a fact not generally known that the M.D. degree of the University of Edinburgh is not recognised as entitling its possessor to become a candidate for a post as physician in any of the medical charities in that city. Who would believe that the medical degree of the University whose world-wide reputation largely depends upon its medical teaching would be so little thought of in its own city? What, it may be asked, is the qualification required of candidates for the office of physician to the Medical Charities of Edinburgh? Is it the degree of some University of higher repute, if such could be found? Not at all; it is the Fellowship at the College of Physicians of Edinburgh, without which no one however able or anxious to devote his time and talents to the treatment of patients in connection with the medical charitable institutions of Edinburgh, can hope to do so. This Fellowship costs over eighty pounds, about sixty of which enters the coffers of the college.

The conclusion of the article we thoroughly agree with.

The College itself is not likely to move in this matter, and the only practicable way in which such a manifest wrong can be done away with is for the Court of Contributors or the Managers of the Infirmary and the several charities in the city to take up the subject. By simply altering their rule as to qualifications which it is necessary for their physicians to hold, the evil would be done away with. By their present rule, which admits only Fellows of the College of Physicians as medical officers, they, perhaps unwittingly, limit the number of candidates for such appointments, seeing that the large sum of money demanded by the College for its Fellowship permits only those who can raise the money to gain the necessary qualification. This is a matter which presses heavily upon the medical profession in Edinburgh, and at the same time makes the Charities of the city run the risk of appointing as their medical officers the wealthiest rather than the best men, so that it deserves the earnest and immediate attention of those who alone are capable of redressing the wrong.

MEDICAL TERRORISM.

LIKE a modern Don Quixote Dr. A. Wilson has set his spear at rest, to have a tilt at windmills and creations of his own fancy. Under guise of attacking medical etiquette, medical laws, and medical journalism, he raises objections, and then to his own satisfaction he demolishes them. This knight errant of the nineteenth century makes war in the name of health science. He has a tilt at us because we gave an extract from the answers he usually favours his correspondents with ; some more samples of which we lay before our readers :—

PETER MAIR.—Try Bayley's cure for piles (17, Cockspur-street, Pall Mall, London, S.W.), which in your case is almost certain to effect a cure. It is a safe and trustworthy remedy.

COLD ONE.—Try inhaling the smoke from Dr. Douglas's Maori Cigarettes, or Marshall's Cubeb Cigarettes, through the nostrils. Dr. Dunbar's Alkaram has also a high reputation in checking nasal catarrh.

T. M. J. MUNRO.—It appears to us that you require a tonic remedy such as strophanthus. This would in all probability do you much good, but it can only be used under medical care. We suggest you should consult another physician (*we can send you address if you desire it, on receipt of stamped addressed envelope*), who will pay more heed to the history of your case than did your former adviser.

DUFFUS.—Try the Trichophile Pomade (advertised in our pages) of the French Hygienic Society, 56, Conduit-street, Regent-street, London, W.

NETTA FAIRBAIRN.—Take a pill containing one grain permanganate of potash, to be made up with Kaolin. Take two of these pills, or two dioxide of manganese tabloids, twice daily, after your food, before the period, and let us hear the result after a brief trial of this remedy.

We did not pronounce a definite opinion upon this form of consultation and medical advice, but hinted that the Medical Council was the proper body to decide this question. We commend to our readers' notice the last answer ; for ourselves we feel utterly surprised at any medical man prescribing permanganate of potash in this way. See also the answer to T. M. J. Munro. In replying to our annotation the editor of *Health* simply resorts to the old devise, "No case. Abuse the plaintiff's attorney." We pass over his libellous definition of the *Provincial Medical Journal*, which is as untrue as his other general remarks, and turn to one of his windmills : (1) He tries a side wind to divert attention from the points at issue, by hinting that we wish to curb the "spread of public instruction and health science." We do nothing of the kind. How is health science benefited by the above quoted answers to correspondents, or by the recommendation of Alkaram, Boköl, etc., "advertised in our pages." This is windmill No. 1. We have no objection to Dr. Wilson recommending Ward's wool clothing, which he can do in the pages of his journal ; our objection applies to the principles of medical etiquette violated, in the general answers given in the pages of his journal. (2) We are favoured likewise with a diatribe against "Allopathic (?) intolerance," in which we have the following extraordinary paragraph :—

"There is evinced, judging from recent utterance of the medical press, a spirit which literary translated, means and implies, that given the *veriest fool who has succeeded in passing a qualifying examination for a medical degree or license*, and the public are to be literary coerced into

consulting him before and above any other practitioner who does not belong to the Allopathic School."

Here is another windmill, raised up to be knocked down. What does Dr. Wilson mean, after his own words, a few lines above ?

"I have," he says, "no sympathy with homœopathy. I believe that system of treatment to be founded on erroneous principles, and upon data incapable of being submitted to rational scientific tests."

We must, therefore, encourage homœopathy, and pander to modern credulity. This is admirable fooling, and not "medical terrorism with a vengeance." (3) One more quotation, and we dismiss this journal for good :

"Various periodicals which, like this journal itself, profess to instruct the public in matters of hygiene, have been singled out as fostering quackery, because they have opened their pages to give *simple remedies* for simple ailments, and because they have endeavoured to diffuse a knowledge of plain health laws and hygienic rules. According to the latest development of the medical terrorism, which would equally suppress homœopathy and frighten the journalism of health out of existence, the public are being deluded and endangered on account of the diffusion of health-knowledge."

Simple remedies forsooth (see the answers *passim*). This paragraph is remarkable for its audacity and for its ignorance. The medical press generally has been the pioneer of sanitary reform. The medical press has done everything in its power to encourage the diffusion of health literature amongst the people. Medical men have published popular guides, popular handbooks, dealing with sanitary questions, and the medical journals have favourably reviewed these books and recommended them. In cities and towns medical men have given health lectures, and in every way aided in trying to awaken a sense of the importance of hygiene, and tell the people how they were sinning against the laws of health. The medical press, and the colleges, have been able to differentiate, however, between legitimate health instruction and quackery. The article in question is written *ad captandum vulgus*, and is unworthy of one who has done good service in the cause of education. Its errors arise from a cause easily discerned, to which we need not allude. It would be wisdom on the part of Dr. Wilson to accept our advice and conform to professional customs, and to utilize the pages now devoted to the indiscriminate recommendation of Alkaram, Boköl, etc., to better purposes. There is ample room for a good health journal.

SOME NUTS TO CRACK.

Mr. RITCHIE, President of the Local Government Board, has put the efficacy of vaccination in a very striking light, and it will be extremely difficult to answer him. Speaking at Sheffield, where small-pox prevailed, he said : "Overwhelming evidence has been given during the course of the epidemic of the enormous value and protection of vaccination. It was estimated from clear evidence that the number of unvaccinated children under ten years of age in Sheffield is about 5,000, and the number of vaccinated about 95,000. Out of the 95,000 children who have been vaccinated, there have been 189 attacks, and two deaths ; out of the 5,000 unvaccinated children, there have been 172 attacks, and

seventy deaths. This is the position of affairs. If we were to assume for a moment that all the children of Sheffield under ten were vaccinated, you would have had 200 attacks, and two and a fraction deaths. But if all the children in Sheffield under ten had been unvaccinated, you would have had 3,277 attacks, and 1,330 deaths, or just exactly 600 times greater mortality. Now, gentlemen, it is almost an established fact that after the age of ten vaccination loses a good deal of its effect; so that the moral is, of this visitation, that all those above ten should be revaccinated, and by that means there is little doubt that in a limited space of time Sheffield will be free of the disease. It gives almost entire and absolute protection to those who are revaccinated, and as an illustration I may tell you that during the time that the Hampstead Small-Pox Hospital was open, only one person out of the numerous employees engaged at that hospital took the small-pox, and he was the under gardener, who by some mistake had escaped revaccination. And I am informed by one of the Medical Inspectors of the Local Government Board who has been down here that out of more than 290 men and boys employed in the Sheffield Post Office, not a single case had occurred. Well now, gentlemen, I think after such evidence it is impossible for even the most rabid anti-vaccinators to gainsay the beneficial results following from revaccination.

THE DEATH METHOD OF THE FUTURE.

A COMMISSION was appointed by the State of New York about a year ago to investigate and report on the most humane and practical method of carrying into effect the sentence of death. We learn from the *Journal of the American Medical Association* that the report of the committee has been presented to the State Legislature. The principal devices already in use are the guillotine, the garrote, shooting, and the gallows. The Commission after receiving some 200 replies from judges, attorneys, physicians and sheriffs, report that the guillotine is too bloody, the garrote too barbarous, shooting too uncertain, and hanging too revolting, and have decided in favour of electricity, thereby ensuring instantaneous and painless death. The Commission also insist that the body of the criminal should be forfeited, the execution taking place without publicity. The Commission proposed that the criminal should be placed in a chair having metallic head and foot rests connected with electrodes; a strong electric current should be passed through the body. The cost of the chair would be fifty dollars; the cost of the electric wires from 250 to 500 dollars; while the cost of maintenance and operation would be nearly nominal.

PTOMAINES.

"LIFE is short, and the art long," said Hippocrates. How true this is we know but too well at the present day, when the art is opening out new fields and new studies. We have but to look at the vast literature built up in a few years on bacteria, and now we have a further field to study

in the ptomaines, an off-study of the micro-organisms. The literature of the animal alkaloids is beginning to swell, and we have a list of names, as those of Dupré, Bence-Jones, Sonnenchein, Rorcth, Schwanert, Sermi, Leibermann, Nencki, Brieger, Villiers, Vaughan, and Gautier, who have discovered or advanced the study of these new poisons. Ptomaines appear likely to come to the front, and we would recommend some of our young English experimentalists to take the subject up. Dr. A. M. Brown has done some good service in presenting Gautier's work to English readers.

THE LONDON MEDICAL PAUPERISATION SCHEME.

In the *Provincial Medical Journal*, March, 1887, and in January, 1888, we condemned in plain terms the so-called Metropolitan Provident Dispensaries, and which better deserve the above name. We are pleased to see that our initiative has been taken up, and that the London practitioners have already held a meeting to protest against, and neutralise the scheme. At a meeting held at No. 1, Sergeant's Inn, on February 3rd, Dr. Paramore in the chair, the following resolution was passed:—"That a committee be formed, with power to add to their number, for the purpose of taking into consideration the scheme of the Metropolitan Provident Association, and they be requested to report to a subsequent meeting of general practitioners the objections to be taken to such scheme, and the steps which it may be desirable to adopt for the improvement of the position of the profession." Dr. Corbyn, 13, Abercorn-place, N.W., is secretary.

SHAM ELECTRIC BELTS.

THE *Electrical Review* has been doing good service in exposing the impostures connected with electric belts, and asks for the support of the medical press in its efforts. We fear the craze or fashion is beyond the pale of medicine to control, though we nevertheless gladly aid our cotemporary, and substantiate, by observation and experience with these appliances, the charges made, that these belts, sold at high prices, are not worth the money. This is all we can do. The world, according to Carlyle, is made up of fools mostly. If £3 3s. or £5 5s. can be obtained for a piece of flannel and a few metal discs arranged in order there will always be enterprising *entrepreneurs* to pick up the offerings of individuals who are so easily duped. Medical men have in every age protested against this and other forms of quackery, but some of the people pass by the way and encourage the charlatans. The lay press publish long and expensive advertisements of various medico-electric appliances, and evidently the demand is equal to the supply. We regret this, as it tends to bring into disrepute true medico-electricity.

COMPETITION IN THE PROFESSION.

In Wigan competition in the medical profession appears to be particularly strong, if we may judge from the doings of several of the medical men there. A few weeks ago a club surgeoncy fell vacant owing to the removal of the

holder of the appointment from the town. The committee of the club altered their rule in reference to radius, to five miles instead of three, and the fee per member per annum they left the same—namely, 2/6. The club numbers in round numbers 400 members, and is thus worth about £50 per annum. Now for this large sum the competition was most extraordinary; circulars were sent out to each club member, and house-to-house canvassing was adopted. One candidate, a hospital surgeon, offered to go six miles, and for the benefit of the members to open a branch surgery two miles from his house. Another candidate offered to do the same in another district; whilst a third candidate enumerated his number of years experience in learning the requirements of club patients, and also the number of his branch surgeries in convenient districts; whilst a fourth to out-do the others—and he succeeded in out-Heroding Herod—sang the praises of his eminently qualified assistant, who lived in the same house with him: he descried branch surgeries as a delusion and a snare, as he said he had tried them, but promised that, “we shall be able and willing to attend to all patients, both from far and near, in the five or six mile limits;” that by carrying a case of urgency drugs and instruments, patients in pain could be relieved on the spot, and wound up his circular with a peroration which is unique, and which we here transcribe for the benefit of our readers. He says: “When there is a main surgery as head-quarters, in the centre of the district, telegrams, urgent messages, and post cards can be sent, and will find one of us on the spot, and ready to drive to where pain and disease are making the attack. One man can only do a certain amount of work, and he cannot be in two places at the same time; so that it is necessary that the assistant be a first-class man, or you will find your mistake out when sickness comes upon you.” After all this there is no wonder that the respectable portion of the profession in the town felt aggrieved at this very “mercantile spirit” of their *confrères*. The Medical Society at a recent meeting, unanimously passed the following resolution: “That it is inadvisable for members of the medical profession to issue circulars, or to use a systematic canvass for club appointments.”

A DUELLING EPISODE.

By the death of Dr. Maddox, of Rapides, New Orleans, there is a link broken between the old America and the new. The following occurrence reads to us like a romance at the present day, but it is true (*New Orleans Medical and Surgical Journal*):—Dr. Maddox died in his ninety-sixth year, and was the last survivor of a famous duel which took place in the year 1835. Dr. Maddox and Samuel Wells, brother of Governor Wells, went out to fight a duel, accompanied by Colonel Crain, Colonel Blanchard, and Major Wright, on the Maddox side; and General Cuney and James Bowie on the Wells side. Bad feeling had existed for some time between these gentlemen. Colonel Crain was even then disabled from a gun-shot wound from

General Cuney. Dr. Maddox and Wells settled their difficulty, and did not fight. But this did not appear to be satisfactory, however. Somehow or other, Colonel Crain, resting his lame arm on the other, fired two pistol shots, one of which killed the opposing party, and the other severely wounded Colonel Bowie. While Bowie was lying on the ground, he managed to grasp Major Wright, who approached him with a sword cane, and literally carved him to pieces with the original bowie knife which on that occasion drew its first blood. Bowie fell subsequently, with Crockell and Travis, at the Alamo massacre in 1836.

THE CASE OF THE CROWN PRINCE.

SIR MORELL MACKENZIE, at the request of the Crown Prince, has placed on record the following report:—

“The general idea is that I am of opinion that the disease from which His Imperial Highness is suffering is cancer; the view, on the other hand, which I have consistently maintained is, that there never has been any proof of the existence of cancer. To enter more into detail: when I arrived in Berlin last May, I stated to my colleagues that in my opinion the appearances seen in the throat were of a negative character—that is to say, that the disease might be either benign or malignant, and that its value could only be determined by microscopical examination. A portion of the diseased tissue having been taken away by me from the throat of His Imperial Highness, it was submitted to Professor Virchow, who could not detect in it anything of a malignant nature. Repeated examinations by Professor Virchow of other portions removed by me yielded similar results. In the month of July, whilst His Imperial Highness was staying in the Isle of Wight, I pointed out to more than one of his august relatives that the danger that I most dreaded was the occurrence of perichondritis at a future date, and three months later this fear was found to be well grounded. At the end of October, and early part of November, entirely fresh symptoms appeared, and at that time the local disease presented an appearance which was consistent with the diagnosis of cancer. It was then impossible to obtain any fresh microscopical evidence in the matter, and I considered it safer accordingly to treat the case as one of a malignant nature. At the same time, however, I drew up and submitted to my colleagues a protocol, in which I stated that although the disease at that moment looked like cancer, I could not agree that the malady was proved to be malignant until a further microscopical examination had been made. The document in which I set forth my views was forwarded to Berlin, to be placed in the State Archives. Although the unfavourable symptoms then present were explicable on the ground of the existence of cancer, yet it was clear to the majority of the physicians at that time in attendance that perichondritis had supervened. In the middle of December, however, the unfavourable signs had passed away, and there were no longer any clinical symptoms of cancer. Microscopical

evidence on the subject was, however, still wanting. This was furnished at the end of January, when a slough was expectorated from the very spot which had presented such a highly suspicious appearance in November. This slough was most carefully and repeatedly examined by Professor Virchow, and the result (which is now published) again shows that cancer could not be detected. To recapitulate: In my opinion the clinical symptoms have always been entirely compatible with non-malignant disease, and that microscopical signs have been in harmony with this view. I need only add that although in nearly every case of laryngeal disease it is possible at the first inspection to form an accurate opinion as to the nature of the disease presenting itself, yet in a few rare instances the progress of the complaint alone permits its character to be determined. Unfortunately, the case of His Imperial Highness is among the latter number, and at this moment medical science does not permit me to affirm that any other disease is present than chronic interstitial inflammation of the larynx, combined with perichondritis.

"San Remo, February 12th, 1888."

WHAT IS GAVAGE?

GAVAGE is the name given to a new system of feeding newly-born children, who are born before term, or who are delicate. The apparatus necessary for the purpose is very simple. Take a piece of gutta-percha tubing about the size of a No. 14 or 15 French catheter. This is fixed on one of the breast shields in common use for sore nipples. The child is placed on the knee of the nurse, with the head slightly raised. The sound is moistened with milk, introduced at the base of the tongue; the child by a reflex act of deglutition will generally draw it as far as the entrance to the œsophagus, if not it is gently conducted there until fifteen centimetres of the sound are introduced. Pinch the sound between two fingers, pour into the cupula two or three tablespoonfuls of milk, and relax pressure until it flows gently into the stomach. The sound must be taken out gently and quickly, and the infant placed in the warm cradle or couveuse. The apparatus must be washed in a solution of boric acid and pure water. The quantity of milk given to the weakest infants is eight grammes every hour. In general, in spite of gavage, the child loses weight for the first few days; but weight soon begins to increase regularly. Gavage carried out according to the rules minutely laid down by M. Tarnier has produced marvellous results and veritable resurrections. Children of six months by the couveuse and gavage have been reared, and M. Tarnier hopes even to arrive some day at the rearing of children born before the end of six months.

New Remedies.

Antipyrine is now frequently employed hypodermically, and for preventing the development of fungoid growths in the solutions used for this purpose the addition of a small quantity of carbolic acid has been suggested. It has been found, however, that carbolic acid causes a

uridity in the solution. Experiments made with the view of preventing this turbidity have shown that it is due to the formation of a compound of the two bodies, and that some other antiseptic must be used instead of carbolic acid, since the latter cannot be added in sufficient quantity to produce sterilization without affecting the strength of the solution of antipyrine.

Erythrophleine, the active principle of sassy or casca bark, has now for some time been known to exert a powerful action on the heart, but there seems reason to believe that another property is possessed by this alkaloid which has hitherto been overlooked. From an African arrow-poison, known as "haya," examined by Dr. Lewin, and which was judged to be derived from *Erythrophleine guineense* by some fragments of bark contained in it, a solution was obtained, which caused complete and prolonged anæsthesia when injected into the eye of a cat. The supposition that this was due to erythrophleine was confirmed by the fact that the solution of haya poison, when treated with sulphuric acid and evaporated to dryness, gave a rose colour like erythrophleine. Dr. Lewin states that immediately after an injection of a 0.2 per cent. solution in the eye, an anæsthesia is set up which lasts from two to two and a half days. Weak solutions cause at first a smarting, which soon passes off, and stronger solutions than the above strength may even cause irritation of the cornea. On the other hand it should be stated that the haya poison gave indications of the presence of a glucoside as well as an alkaloid, and that the anæsthetic property may be due to the glucoside.

Resorcin may now be added to the list of remedies, already a numerous one, employed for sea-sickness. In a note in the *Lancet* (p. 39), Dr. Andrew states that, if given early before vomiting, a single dose of ten or twenty grains removes the giddiness and nausea, and enables the patient to sleep comfortably. In more difficult cases larger doses have to be given two or three times a day. Dr. Fronstein has also found it useful in cases of laryngeal tuberculosis. He employs it to allay the pain and distress caused by ulceration of tubercular origin.

Embelia ribes, an East Indian plant, the fruit of which has been proved by European practitioners to possess considerable value as a remedy for tape-worm, has been submitted to a chemical examination by Mr. C. J. H. Warden, with the view of isolating the active principle. On treating the fruit with chloroform, by percolation, a yellow crystalline principle was obtained, which gave a red reaction with alkalis. This was proved to possess the properties of an acid. From the chloroformic solution it can be removed by caustic soda. On neutralising the alkaline solution with an acid, the new acid, to which Mr. Warden has given the name of embelic acid, is precipitated of a yellow colour. It is soluble in alcohol, but scarcely soluble in water. It is not yet certain that the activity of the drug is due to the embelic acid, but evidence will be shortly forthcoming on this point.

Quebracho has been lately employed by Bourdeaux as an external application in the form of fluid extract. Applied to recent wounds it causes a transient pain at first, and acts much like collodion, rapid healing taking place. Good results also follow its application to burns or frozen parts. In the course of an hour the fluid extract hardens and forms a brown crusty layer, which cannot be easily removed unless warm water be used. When the crust falls off the wound is invariably healed. The quebracho used by Bourdeaux is probably the red quebracho bark (*Loxopterygium Lorentzii*), which yields a red astringent extract very different to anything that can be obtained from the bark of ordinary or white quebracho (*Aspidosperma Quebracho*).

Benzoate of Sodium has recently been recommended by Dr. A. S. Partzovsky, of Moscow, for the treatment of uræmia. In ten cases treated by him, three of which were suffering from interstitial and seven from parenchymatous nephritis, the drug was given hourly, in doses which amounted during the day to one or two drachms. It was administered in various ways—in solution, wafers or capsules, or enemata where internal administration was impossible. Nine patients recovered and one died. Dr. Partzovsky believes that benzoate of sodium shortens the attacks, the convulsive attacks gradually ceasing, and the

patient falling into a deep sleep. The patients usually awake in a state of full consciousness. Albuminuria generally disappears altogether. If given when the symptoms—viz., headache, dilatation of the pupil of the eye, and sickness—first appear, the attack may often be entirely ward off.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

On the Transmission of Rabies from Mother to Fœtus through the Placenta and by the Milk (*Centralblatt für Chirurgie*, No. 46. *E. Perroneito e Carita*, from *Giorn. dell. accad. d. Med.*, Torino, 1887).—A pregnant guinea-pig, five days after inoculation, brought forth four premature young ones, which lived only a short time, the mother dying after a few days from undoubted rabies. The fœtusses were placed in a ten-per-cent. dilution of sulphuric acid. The spinal cords were used in the Pasteur method for the inoculation of a guinea-pig which remained healthy, while another died with symptoms of rabies. From the spinal marrow of this animal two guinea-pigs and one rabbit were vaccinated, and died respectively on the seventh, eighth, and eleventh days with paralytic rabies. Hence the transmission from mother to fœtus was, according to the authors, proved. With reference to the transmission of the poisons by the milk, two pregnant rabbits were inoculated; one aborted, the other had two healthy young ones which were suckled by the infected mother. The mother died from rabies eight or nine days subsequently. The young ones also died in a few days. From their spinal cords a rabbit and a guinea-pig were inoculated, both which died rabid, confirming the diagnosis with reference to the mother's milk; but it is possible that the poison may have been conveyed through the placenta before birth.

Spurious Hydrophobia (*L'Union Médicale*).—M. Mernch, at the Société de Médecine de Paris, related the case of a spirit drinker who, whilst drinking, saw in his glass a sediment, at which he took fright, and was seized with constriction of the throat followed by headache, a general stiffness, and sense of fatigue in his limbs. This occurred on a Sunday. During the following night, and on Monday and Tuesday, he was sleepless, oppressed with a feeling of suffocation, spasms in the throat, a horror of liquids, which he threw away with the glass. His appearance was that of restlessness, with a fixed haggard glare, pupils dilated, speech short and interrupted, and shortness of breath. The offer of liquids was rejected with affright, and brought on a sense of suffocation and tightness of the throat. Light and brilliant objects were distressing to him. He died on the Tuesday evening, after having been the subject of a furious delirium, with extreme agitation, uttering loud cries. He was profusely salivated—spitting, and biting his clothes, and endeavouring to bite his attendants. He presented all the characters of furious hydrophobia, but he had not been bitten by any animal. He had, however, experienced previous attacks of the same kind, at long intervals, and it transpired that he belonged to a family in which insanity existed.

The Micro-organisms of Varicella. By Guttman, Berlin (*L'Union Médicale*, November, 1887).—In one case, the serosity of which was cultivated on Agar-agar, Dr. Buttman found three varieties of micro-organisms: (1) *Staphylococcus pyogenes aureus*. (2) *Staphylococcus viridis*, the yellowish-green colonies of which did not liquefy gelatin. (3) *Staphylococcus blanc*, the cultures of which had a pearly lustre. In a second case the author found only two of these microbes. In a third case the *Staphylococcus nacré* was found, with another which he did not succeed in isolating.

The value of Tincture of Strophanthus (*The Journal*, Chicago, January 14th, 1888, from *Deutsche Medicinische Wochenschrift*, 1887).—Dr. Hochhaus thus summarizes his observations of the effects of tincture of strophanthus:

1. For valvular weakness in the stage of compensation disturbance, tincture of strophanthus is an excellent remedy in certain cases, to retard, strengthen and regulate the cardiac action. The retardation occurs first while the regulating effect only takes place, as a rule, after a few days. Dyspnoea and oedema are promptly relieved. But the favourable effects, in about one-half the cases, do not appear with the regularity and safety peculiar to digitalis; and in most cases in which strophanthus failed digitalis was effective. Digitalis has, generally, a quicker and more thorough effect, especially in causing diuresis, while strophanthus affects a disturbed respiration far more favourably. It is more difficult to indicate strophanthus than digitalis in cases of valvular

weakness, so that it is almost impossible to say beforehand in what cases strophanthus will probably be successful.

2. In chronic degenerations of the cardiac muscle, with usually a small, frequent, and irregular pulse, great difficulty in breathing, and oedema, tincture of strophanthus may be relied on.

3. In acute and chronic nephritis the effect of strophanthus is not so marked as in the above mentioned affections. The dyspnoea often yields to its influence as in the other diseases, but the diuresis and oedema are not favourably affected by it.

4. In cases of palpitation and apnoea of nervous origin strophanthus often gives marked relief.

5. Oedema of a cachectic character may be also favourably affected by tincture of strophanthus.

6. In some cases the drug has secondary effects on the digestive tract, causing a loathing of food, followed by vomiting after eating, and sometimes by severe diarrhoea. But, as a rule, the aversion to food is the only disturbance, and passes off when the stomach becomes used to the drug.

7. Hochhaus advises to begin with doses of gtt. vj, t. i. d., in a tablespoonful of water or wine, and to add gtt. ij daily to the dose until the effect is obtained; though it is not advisable to give more than gtt. xx t. i. d. Gtt. iij t. i. d. is the proper dose to begin with for children, but the doses should not exceed gtt. v, t. i. d.

8. The effect usually appears on the second or third day, and generally lasts a week or two weeks, though there is considerable variation. Hochhaus has never seen a cumulative effect, even after long use of the drug.

9. While strophanthus cannot lay just claim to all the praise bestowed upon it, it is valuable as an occasional substitute for, and ally of digitalis.

On Ocular Cephalalgia. By M. Parinaud, Paris (*Ophthalmic Review*, January, 1888: from *Rev. d'Ophthalm.*, December, 1887).—The author divides all cases of headache arising from use of the eyes in two chief classes, (A) *ocular cephalalgia*, properly so called; (B) *neuro-ocular cephalalgia*. Class A includes all cases in which the muscular apparatus of the eyes is at fault, and two sub-divisions naturally suggest themselves: (1) Cases in which there is defect of the internal recti (*muscular asthenopia*); (2) cases in which the ciliary muscle is more or less incapable (*accommodative asthenopia*). In both conditions sustained use of the eyes gives rise, among other symptoms, to headache, usually supra-orbital or frontal, but often becoming rapidly general, which lasts a varying time after the cessation of work. In muscular asthenopia the pain is frequently preceded by a sensation of fatigue, which patients compare to the tired feeling following great muscular exertion, and which they localise in the inner side of the eyeballs. At other times there is an ill-defined *malaise*, or a feeling of tension or pressure in the orbits, and in certain cases nausea and vertigo. Parinaud includes in class B all cases of asthenopia or cephalalgia produced by use of the eyes, in which neither hypermetropia, astigmatism, nor insufficiency of the internal recti can be found. The cause, he thinks, rests with the nervous system. Hysteria, neurasthenia, adolescence, excessive mental application, and an arthritic diathesis are mentioned as conditions in which neuro-ocular cephalalgia is met with. The cephalalgia of adolescence, which has been investigated by Keller and Blache, occurs between the ages of fifteen and eighteen, and is more frequent in males than females. The pain in these cases is peculiarly frontal, and sometimes localised as two painful points at the roots of the eyebrows. Use of the eyes always intensifies the pain. Correction of any error of refraction which may be present has but little effect, and the only successful treatment is complete rest of eyes, and improvement of the general health.

A case of Tubercular Inoculation through performance of the rite of Circumcision (*Centralblatt für Chirurgie*, No. 46).—The rite was performed on the eighth day. The wound (according to the ordinary custom) was several times sucked by an old man. About the fourth week thickening of the frænum, with enlargement of the inguinal glands appeared. Syphilis was suspected, but antisyphilitic treatment proved useless. Suppuration of the inguinal glands followed. Soon afterwards an abscess of about the size of a cherry appeared in the right gluteal region. The diseased surface of the penis, and the discoloured edges of the inguinal abscess, were removed by the knife. Microscopical examination of the diseased parts showed abundance of miliary tubercle and tubercular bacilli.

Guaiacol, a substitute for Creasote (*Journal de Médecine de Paris*, 29th Janvier, 1888).—Guaiacol (C⁷ H⁸ O³) is the principal element of creasote. Sahli recommends it to supersede the uncertain action of the ordinary more or less pure creasote. It is obtained by distillation from beech creasote, whence it may be obtained in large proportions, as much as ninety per cent. The distillate is shaken several times with a weak

solution of ammonia and redistilled; it is then dissolved in an equal volume of ether, with the addition of slight excess of alcoholic solution of caustic potash. The precipitate which is formed is then to be washed in ether, crystallised in alcohol, and lastly saturated with diluted sulphuric acid. The guaiacol separates in the form of a liquid, having an agreeable odour, with a sp. gr. of 1.117 at 55° F. It requires to be kept protected from light.

On the Parasitic Nature and the Treatment of Furunculus and Anthrax (*L'Union Médicale*, Janvier 21st, 1888).—Assuming the parasitic nature of furunculus, M. Verneuil dealt much upon the value of pulverisation of the antiseptic solutions of phenic or boric acid, repeatedly applied, which, he asserts, renders abortive the inflammatory process. He not only advocates, hereby, the cure of the boils, but in order to prevent their recurrence urges the antiseptic internal treatment proposed by M. Bouchard, which consists in the administration of naphthol, salicylate of bismuth, and magnesia, in small doses, every four hours. The latter treatment alone in one instance was successful without the use of the spray. The same principles of treatment are applied by M. Bouchard to the treatment of carbuncle.

Permanent Polyuria following Fracture of the Base of the Skull. By A. Berri (*Centralblatt für Chirurgie von Spérimentale*, No. 5).—A man, aged thirty-six years, from a fall down stairs sustained fracture of the base of the skull. At the end of a fortnight he was so far recovered that the original symptoms were no longer noticed. The only complaints of the patient were deafness on the left side and occasional pain on the right side of the occiput. Polyuria was now noticed. On the 17th day, 3,800 g. and on the following day 4,100 g. of acid urine were measured. Sp. gr. 1.010; no sugar or albumen. In the course of the following week the quantity of urine fell to 3,000 gs. and then gradually fell to the normal quantity. The patient died of pulmonary disease about ten weeks later. The only noticeable lesion of the bones was a darkish line of from three to four lines in length in the posterior cranial fossa. Corresponding to this the dura mater was covered with a thin yellow deposit to which to the extent of a mark was adherent to the nervous substance. Nothing abnormal besides this was seen on the brain, nor in any other organ.

The Therapeutic Uses of Boric Acid. By M. Gaucher (*L'Union Médicale*, 31st Janvier, 1888).—M. Gaucher has put to test the toxic powers of boric acid by administering it to guinea-pigs. To these animals, of the weight of about 300 grammes, he gave, daily, fifty centigrammes during fourteen days, without any injurious effects. It is not caustic, is tasteless, colourless, and inodorous. It has been found an efficacious infectious impetigo application; in the form of ointment, after poulticing. In tuberculous ulcerations, also, M. Gaucher has found this remedy very useful—and has moreover employed it with advantage, internally, in phthisis. Boric acid passes rapidly into the urine and hence is of service in vesical maladies, as chronic cystitis and enlargement of the prostate.

Ocular Symptoms in Insular Sclerosis and in Ataxy. Charcot, Paris (*Ophthalmic Rev.*, January, 1888, and *Rev. d'Ophthalm.*, November, 1887).—One of the most common motor disturbances in ataxy is paralysis of the external rectus, or muscles supplied by the third nerve. This is of rare occurrence in disseminated sclerosis. In this form we find paralysees whose cause must be sought in the central nuclei. These are not peripheral paralysees, such as occur in ataxy, but lesions whose objective signs are defects of coördination, shown by paralysis of the associated movements of the eyes; when looking to the right or left, the margin of the cornea fails to reach the inner or outer commissure, or there is an appreciable lagging in the rotation of one or other eye. The earliest symptom of this condition is an inability on the part of the patient to fix on an object with precision, and a, consequently, vague look. Oscillatory movements of the eyes occur, closely allied to those of nystagmus, and at first there may be slight diplopia. A study of the movements of the iris is chiefly valuable in relation to ataxy. One pupil is sometimes contracted to a pinhead in size, while the other is dilated—a condition seen only in tabes or general paralysis of the insane. A more important indication, however, is that known as the Argyll-Robertson pupil, the pupil showing no reaction to light; well marked contraction occurring in association with convergence and accommodation. It is this contrast between its action to light and accommodative efforts which constitutes the Argyll-Robertson pupil. Atrophy of the optic nerve, with its characteristic ophthalmoscopic appearances, will also be seen by examination of the fundus, in tabes. This atrophy is frequently the first sign of ataxy. Amaurosis may also be present in disseminated sclerosis, but unaccompanied with any ophthalmoscopic change beyond pallor of the papilla. It is, moreover, a defect which may disappear, as the axis cylinders are not destroyed the functions of the nerve may be re-established. In dis-

seminated sclerosis there is sometimes a contraction of the field of vision, as in hysteria.

New Researches on the Poison in Expired Air (*L'Union Médicale*, 21st Janvier, 1888).—At a meeting of the Academy of Sciences (Jan. 16th) MM. Brown-Sequard and d'Arsonal showed that by condensing the aqueous vapours given off by the lungs of men and mammiferous animals in good health, an extremely powerful poisonous liquid is obtained capable of causing speedy death. This poison they find to be an alkaloid, and not, as supposed, to consist of a series of microbes. This poison injected beneath the integuments caused death as rapidly as when injected into the vessels. The animal dies without convulsions, and upon examination the *vena cava* and large vessels are found to contain red blood while the left ventricles and arteries contain but a small quantity of dark blood. The influence of the poison, the authors consider, is expended on the base of the brain. This fluid, exposed to a temperature of 212° F. does not lose, but rather gains strength. It is, therefore, inferred that the deleterious effects are not due to microbes. Further experiments and researches prove the poison to be analogous to ptomaines and leucamines.

Prophylaxis of Ophthalmia Neonatorum (*Centralblatt für Gynäkologie*, 28th Januar, 1888).—The plan here advocated is that of Dr. Von Kaltenbach, which consists in washing the vagina, previous to and after delivery, with a solution of sublimate, 1 in 3,000, and mopping the eyes of the infant with the same, taking care not to introduce the liquid between the lids. Dr. Nebel reports that he had treated in this way 330 infants, among which number not one instance of ophthalmia occurred. In two or three cases through inadvertence the inflammation occurred, but was arrested speedily by the application of cold water. This antiseptic treatment is not only of advantage for infants but is also of great benefit in protecting the maternal organs from infectious maladies.

Heredity manifested in Cataract. By G. A. Berry, M.B. Edin. (*The Ophthalmic Review*, January, 1888).—A series of cases are mentioned by Dr. Berry, including fifty-five individuals belonging to five generations—twenty-eight were females, twenty-seven females. Twenty had cataract, eight males and twelve females. The hereditary tendency was therefore more strongly marked in the females. The predominance may not be so great as may appear, from the impossibility of tracing the descendants of some of the cataractous generations. In respect of preponderance of heredity, transmission through the female differs from most which have been published. This may possibly be on account of the different nature of the cataract, whether senile or juvenile. In true congenital cataract Dr. Berry has never found any evidence of heredity. No other disease besides cataract appears to have been transmitted at the same time. A point of general rather than special interest, in connection with heredity, is the tendency for the cases to appear in succession, showing a greater tendency to inheritance from the mother, as far as cataract goes, at one particular time of child-bearing life than at others. In no instance had the eldest girl escaped.

Poisoning by Phosphorus detected Three Months after Death (*Journal de Médecine de Paris*, 1 Janvier, 1888: quoted from *Vierteiljahrsschrift für Gerichtliche Medizin*).—The case referred to is supposed to be the first instance in which chemical analysis has detected the fact of poisoning by phosphorus three months after death. All the organs in the body contained the product of oxidation—phosphoric acid. Small quantities of antimony and arsenic were also detected. It was ascertained that rat-poison had been administered with criminal intention.

A case of Total Absence of Uterus, Vagina normal. By Dr. Steinshneider, Frauenbad (*Centralblatt für Gynäkologie*, 28th Januar, 1888).—The subject, in this case, was twenty-eight years of age, had been married five years, had never menstruated. For last three years had at intervals suffered from general failure of health with loss of appetite, flatulency, and constipation. For these complaints, to which she attributed her childlessness, she sought medical advice. She presented an anæmic aspect, of middle size, with small but well shaped bosoms, and not very broad pelvis. The external genital organ normal, the clitoris small, the labia loose and free from thickening—the vagina eight centimetres in length (=about three inches Eng.) terminated in smooth *cul de sac*. A combined vaginal and rectal examination showed a total want of uterus, and, as there seemed to be no doubt, an entire deficiency of ovaries. She had never experienced menstrual pains, neither had she active desire for sexual intercourse, on her own account; she was not conscious of any voluptuous feelings which doubtless is attributable to the absence of ovaries.

Removal of a long fixed Pessary (*Centralblatt für Gynäkologie*, 28th Januar, 1888).—At a meeting of the Gynecological Society of Kief (May 9th, 1887), the case was related of a removal, piecemeal, of

a pessary from the vagina of a patient, who had worn it uninterruptedly for twelve years. The use of an occasional injection had been employed. No special inconvenience or pain had occurred, but the persistence of an offensive discharge had occasioned application for medical advice. The pessary, which had become black, was of annular form, of light wood, about eleven inches in circumference, and a diameter of about three and a half inches. In the posterior wall of the vagina was a deep groove, the walls of which appeared of a schirrous nature.

Abscesses resembling Glanders induced by Hypodermic Injections of Morphine (*L'Union Médicale*, 17th Janvier, 1888).—M. Fereol relates the case of a man who presented on his body a number of abscesses, in the pus of which were seen bacilli, in form resembling those of glanders. Inoculations of these in a donkey proved negative. The man had not suffered from glanders, although he had been concerned with glandered horses. It was discovered that this man was in the habit of using hypodermic injections of morphine, as frequently as three times a day, by which a cacheatec condition favouring the formation of abscesses had been induced.

On the Treatment of Traumatic Separation of the Epiphysis of the Head of the Humerus. By Dr. von Helferich (*Centralblatt für Chirurgie*, 21 Januar, 1888).—This rare accident is usually associated with dislocation of the joint, and is often wrongly treated through the true nature not being recognised. In a case related by Dr. von Helferich the patient, sixteen years of age, in wrestling was thrown to the ground on to his left shoulder. The round head of the bone could be felt in its normal position under the acromion. The end of the shaft of the bone could be detected, forwards and inwards, under the coracoid process. A shortening of the arm by a centimetre and a half was found. The lower portion of the humerus was seen to be inclined outwards and downwards. Forcible extension downwards produced a slight crepitation. An incision into the joint was made, and the upper end of the bone; by an enlargement of this narrow "button hole" in the axilla, the two portions of bone were affixed together by a long needle. The ligature brought between the edges of the wound was removed in eight days. Union took place without any drawback, and the shoulder joint rapidly recovered its normal movements.

II.—NOTES FROM RUSSIAN JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

On Hermaphroditism.—In the *Vratch*, No. 50, 1887, p. 962, Dr. J. Bondareff, of Kiev, describes an interesting case of pseudo-hermaphroditism, of Foerster's "transverse" variety, which he happened to meet with in Professor Troitzky's female syphilitic wards in the Kirillovsky Hospital. The individual in question was admitted to the hospital (on account of constitutional syphilis) as a "peasant woman, aged thirty-five, single." The patient was found to be well made, fairly muscular, measuring 161 centimetres in height, and possessing rudimentary, but quite distinct beard and moustaches, and harsh and rough voice. There were present middle-sized mammary glands. The distance between the anterior upper iliac spine measured twenty-six centimetres, that "between the iliac cristæ" also twenty-six, and the diagonal conjugata eleven. The genital slit was three centimetres long. The major labia were middle-sized, the right being somewhat larger than its compeer. Each of them contained an oblong body of the size of a male testicle, which was situated in the upper part of the fold in the right labium, and close to the outer opening of the inguinal canal in the left one. A cord, of the size and consistency of a spermatic funicle, was found to be attached to the upper end of each testicle-like body, to pass up into the pelvic cavity. The minor labia were developed but very imperfectly, and "represented something like appendices of the prepuce of the clitoris." The latter measured six centimetres in length and four and a half in its circumference, and most closely resembled a small penis with a glans, corona, foreskin, and frenulum, but without any urethral meatus. The orifice was situated (to judge from the author's drawing) considerably lower down, close to the upper angle of the vaginal opening, and had the shape of a "patent oblong slit which very easily admitted a forefinger, and even two fingers." The vagina was not longer than three centimetres, and was terminated by a blind pouch with a small rudiment of a womb. Not a trace of any ovaries (or of a hymen) could be detected. The patient never menstruated. According to "her" statements, "she" has a regular sexual intercourse with "her" sweetheart, but performs successfully coitus also with women. Taking into consideration an extreme shortness of the vagina on one side, and a strikingly patent condition of the urethra on the other, Dr. Bondareff comes to the conclusion that the person's coition with the male sweetheart takes place through the urethral canal.

In the *Russkaia Meditzina*, No. 43, 1887, p. 710, Dr. Lükomsky, of

Prilükii, publishes a brief note on a case of what seems to be a rare specimen of true hermaphroditism. A newly-married peasant couple requested him to tell them whether the bride was a woman or a man. The examination showed that the bride possessed both the male and female sexual organs. The former were represented by a penis as thick and nearly as long as a man's thumb, but void of any prepuce or urinary orifice, and by a well-developed scrotum with two testicles of the size of a pigeon's egg. There was found also a complete set of female genital organs—viz., breasts (under-sized), clitoris, with an urethral orifice beneath, major and minor labia, and a genital slit with a recently ruptured hymen (with caruncles). The vagina was fairly spacious. A small-sized uterine cervix could be seen through a speculum. The individual never menstruated, but had sexual intercourse both with men and women. The patient, however, feels an intense aversion ("hatred") towards men, but is extremely fond of women, the sexual act with whom is terminated by discharge of a whitish fluid from the vagina. A divorce was at once granted to the couple by the Most Holy Synod.

Poisoning by Chlorate of Potash.—At a recent meeting of the St. Petersburg Society of Russian Practitioners, Dr. R. N. Manotzkova, a lady physician attached to the Obükovsky Hospital, read an instructive paper (*Vratch*, No. 48, 1887, p. 938) on two female cases of suicidal poisoning by chlorate of potash. One of the patients, a well-made and nourished, previously healthy domestic servant of seventeen, swallowed one ounce of the crystallised salt, mixed with some water, about 1 a.m., the first symptoms (nausea and vomiting, with crystals in the dejecta) making their appearance as late as 3 p.m. On examining the girl about seventeen hours after the ingestion of the poison, the author found a cyanotic discolouration of the face and hands, as well as a distinct icteric one of her scleræ and integuments, a considerable enlargement and tenderness of the liver and spleen, a dark brown discolouration of the (scanty) urine, with intense albuminuria, dark brown fine-granular casts, sp. gr. 1016, a faint acid reaction, and voluminous cinnamon brown deposit, a numerical increase of leucocytes, as well as numerous microcytes in the blood (from a finger). Immediately after her admission, a washing-out of the stomach was made and a purgative administered. During the first nine days the daily amount of her urine oscillated between 200 and 600 cubic cc., but on the tenth it rose to 1,200. The sediment disappeared from the urine on the fourth day, albuminuria on the fifth, a brown discolouration, however, only on the tenth, while the liver returned to its normal state on the thirteenth day. Cyanosis and jaundice were losing their intensity but gradually. The temperature remained normal all through, the pulse varying between sixty and one hundred, and breathing between eighteen and thirty per minute. The girl left the hospital quite well (except some enlargement of the spleen) on the eleventh day. Not so luckily the other case terminated, though the patient—a merchant's daughter, aged twenty-six, of a middling build and nutrition—had taken only four drachms of the salt (also mixed with water, late in the night). Several hours after its ingestion, there appeared nausea, vomiting, diarrhoea, agonising abdominal pains, to which about the third day hiccough and severe headache, and still later on, also jaundice, intense itching all over the body, nasal bleeding, and general excitement added themselves. She was brought to the hospital not earlier than on the seventh day of the toxic symptoms. On admission, beside the symptoms just enumerated, there was found also suppression of urine, the daily amount being then only 100 cubic cc. (after a complete anuria during the sixth day). The urine was turbid, brown, acid, albuminous, of sp. gr. 1013, with epithelial cells, casts, and hæmoglobin. The girl died on the ninth day after her deed. On the *post-mortem* examination, there were found anæmia and oedema of the brain, slight oedematous infiltration of the lungs, with congestion of their lower lobes, transverse enlargement of the heart, with dark fluid blood in its cavities (as well as in systemic blood-vessels generally), a normally-sized but somewhat firm liver, slight enlargement, anæmia, and increased density of the spleen, with Malpighian bodies of the size of a millet seed, enlarged and flabby kidneys with congested pyramids. Under the microscope the renal vessels proved to be engorged with fluid blood. The epithelial lining of the straight and convolute tubules was opaque and granular, while their lumen was at many spots densely blocked up with a fine granular dark brown detritus, and fragments of red blood corpuscles. A similar fine granular *débris* was present also in the bone-marrow. The splenic blood vessels presented hyaline degeneration, while numerous splenic, as well as hepatic cellular elements, showed a fine granular disintegration in its various stages. Dr. Manotzkova thinks that her patient died from acute uræmia.

[In the *St. Petersburger Medizinische Wochenschrift*, No. 10, 1882, Dr. Lingen records the case of a student of the St. Petersburg Mining School, aged eighteen, who, when suffering from catarrhal angina, tried to treat himself by assiduously gargling his throat with a saturated solution of chlorate of potash. Since the unfortunate youth regarded

the salt as a quite harmless substance, he not only retained the gargle in his mouth and pharynx for a long stretch of time on each occasion, but even swallowed the fluid, in which, in addition, "a mass of fine crystals of the salt was suspended." Within a few hours since the beginning of this self-treatment, there appeared intense cyanosis of the integuments and mucous membranes, weakness of the cardiac action, incessant nausea and vomiting, general excitement, extreme anxiety and oppression, prostration, and intense albuminuria, with broken-up red blood corpuscles in the urine. Later on, the latter abounded also with blood casts and epithelial cells of the renal pelvis, while there supervened sleeplessness, hiccough, backache, and pain in the renal regions. On the seventh day the patient died in collapse. No necropsy was allowed. Dr. Lingen thinks that the symptoms seemed to furnish a support to Professor Binz's view, according to which the toxic effects of KCO_3 depend upon a destructive (oxidising) influence produced by the salt on the blood in general, on hæmoglobine in particular.

Another fatal case of an accidental poisoning by KCO_3 in St. Petersburg is mentioned in Dr. Viatcheslav Afanasieff's valuable work ("St. Petersburg Inaugural Dissertation," 1885, pp. 72, with 9 figures), treating this important subject. No details are given, except that at the *post-mortem* examination the urinary tubules were found to be blocked up with blood casts and detritus. Dr. Afanasieff was able to collect from the international literature (British, American, German, French, and Russian) as many as fifty-one cases of the chlorate poisoning, with forty five deaths and six recoveries. As is known, the fact of the chlorate being a pretty powerful poison had somehow remained hidden from the professional eye up to 1855, when Dr. Chevallier published his sensational case of a Tulle umbrella maker. The man, having mistaken the chlorate for sulphate of magnesia, took twenty grammes, repeated the dose on the next morning, and died about the evening during an attack of violent general convulsions. In 1858, Dr. Fountain, of Davenport, a noble seeker of scientific truth, took about thirty or forty grammes of the salt, in order to study its biological action on himself. The martyr of science died from complete anuria and intense gastro-intestinal inflammation four days later. These two so striking cases opened at last a toxicological chapter in the literature of KCO_3 . They were soon followed by those of Kuester, Professor Jacobi, Marchand, Hofmeier, Wegscheider, Manouvrier, Billroth, Brenner, Baginsky, Gesenius, Satlow, Riess, Tillner, Bohn, Broesicke and Schadewald, Neuss, Leichtenstern, etc., as well as by special experimental researches carried out by Marchard, Bridges Adams, S. Lebedeff, Mering, Binz, Isambert, Podkopaieff, and Afanasieff. The latter author undertook his careful experiments (on ten dogs, in Professor N. P. Ivanovsky's laboratory) mainly with the object of studying morbid anatomic lesions brought about by toxic doses of KCO_3 . In three of the cases—in one of which ten, and in another six, grammes of the salt (dissolved in one hundred cubic centimetres of water) had been introduced into the peritoneal cavity, while in the third forty cubic centimetres of a 10 per cent. solution (four grammes of KCO_3) had been injected into the distal end of a divided femoral artery—a fulminant intoxication took place, the animals dying in respectively forty, eighty, and five minutes, with such symptoms as a sudden failure of the cardiac and respiratory action, vomiting, and collapse. In another group of three cases the animals died on the fifteenth, ninth, and seventh day, the respective total doses of the salt (administered internally) being 125, 49.4, and 50.4 grammes. A third group included cases of chronic poisoning, with total (internal) doses of 40.5 and 190.0 grammes, death ensuing on the seventeenth and fifty-ninth day. The outcome of Dr. Afanasieff's important researches may be condensed thus:—1. In *acutest* cases (*intoxicatio acutissima*), the cardinal changes are disintegration and dissolution of hæmoglobin, its transformation into a methæmoglobin-like modification, breaking up of red blood corpuscles, and an acute parenchymatous degenerative process in all parenchymatous organs of the body, "but especially in the nerve-muscular apparatus of the heart." Death is caused here by so profound a deterioration of the blood, and by cardiac paralysis. 2. In *acute* cases, simultaneously with the changes just stated, there takes place a gradual (but rapid) accumulation of the blood detritus in the liver, spleen, lymphatic glands, bone marrow, and kidneys. The urinary tubules become by degrees blocked up, and absolutely impassable, the renal (secretory) functions steadily fail, and the products of metabolism accumulate in the system, to rapidly give rise to an uræmic state. The fatal issue is accelerated by a swiftly progressing degenerative process in all parenchymatous organs, including the kidneys, where there are observed an acute exudative inflammation of the Malpighian glomeruli, with ever-increasing albuminoid deposits in Bowman's capsules, and an acute parenchymatous inflammation of the epithelial lining of all urinary tubules. 3. In *chronic* cases, there are met regressive and atrophic changes in the organs named above. In the kidney, a parenchymatous inflammation of the epithelial covering of urinary tubules and glomeruli is soon followed by intense and extensive

interstitial inflammatory changes, death being caused by usual consequences of a true nephritis. 4. In *all* cases of poisoning by chlorate of potassa, the blood rapidly assumes a most characteristic chocolate colour. The same discolouration, however, is caused also by chlorate of soda, and by all chlorates generally, and seemingly also by nitro-benzol. Dr. Afanasieff emphatically draws the attention of the profession to the powerful toxic properties of the drug which finds so extensive a use in the daily medical practice, and is still regarded by the non-professional public, and even by an average practitioner, as a pretty "innocent" chemical compound. Like Professor Th. Husemann, the author urges that the maximal internal dose for an adult must not surpass two grammes *pro dosi*, and eight grammes *p. die*. How freely the salt is employed by the community in Russia one might judge from the fact that two of the St. Petersburg chemist's shops sell, without any medical prescription, each from 240 to 280 pounds of KCO_3 yearly. In the *Fortschritte der Medicin*, September 1st, 1883, the editors, referring to an alarming enrichment of toxicological casuistics with new and new instances of the chlorate poisoning, recommend the utmost caution even when the drug is used as a gargle. The solution must be labelled—"Caution!" The practitioner must invariably warn the patient and his friends in regard to grave consequences which might follow his swallowing the gargle, etc. In the *Vrätch*, No. 37, 1883, p. 592, Professor V. A. Manassein emphatically endorses that recommendation, and in addition, strongly advises "to altogether discontinue any internal administration of the drug; for, generally speaking, there do not exist any serious or firmly-established indications for its use in that way."—*Reporter*.]

III.—EXTRACTS FROM SPANISH AND OTHER MEDICAL JOURNALS.

TRANSLATED BY DR. G. CADOGAN-MASTERMAN.

Fracturas del Cráneo. By Dr. D. Enrique de Areilza, Barcelona, 1887.—The series of articles on "Trephining in cases of Fracture of the Skull," published in the *Revista de Ciencias Médicas*, and of which a summary appeared in the April, May, and June numbers of this journal in 1887, has been published by the author in a collected form, and two cases added of great interest—the first especially so from its bearing on the operative treatment of epilepsy, and some unusual phenomena during anæsthesia. Severo González Gil, thirty-nine years of age, was struck on the forehead by the stopper (*obturador*) fired from a fowling-piece, over the right eyebrow, two centimetres above the edge of the orbit, in the year 1876. The medical men who then saw him found a contused wound and an evident depressed fracture of the skull, but as the symptoms seemed to belong to the wound only, they contented themselves with allowing it to heal without raising the bone. Ten days afterwards, although fever set in with furious delirium, the same gentlemen still declined to meddle with the fracture; but under the customary purging and salines the meningitis subsided, and the man returned to work with no other trouble than occasional convulsive attacks, which, slight and infrequent at first, gradually developed, however, into well-marked epilepsy. For the last ten years they had continued with variable duration and intensity; for the first seven always in the night, and never more than once a month, then for a time more frequently and severely, but only to disappear apparently altogether; but during the last two years the fits had been extremely frequent, until at last they recurred daily, and in a most distressing form. During this long period the man had been under treatment, both at home and in hospital, at Madrid and Zaragoza—always, however, for the induced epilepsy, never for its causal injury.

When he came under the care of Dr. Areilza in November, 1886, the attacks were diurnal, and were accompanied with great restlessness; sleep was disturbed by terrifying dreams, and when awake the man was incessantly champing his jaws. At the moment of attack he would become suddenly cyanotic, the whole body fixed and rigid—on the right side first—then he would give a piercing shriek, and fall to the ground insensible. In a short time the blueness of the skin would be succeeded by extreme pallor, and the tonic contraction give way to violent convulsions, the lips were covered with yellow foam, and the tongue often severely bitten. There was also a convulsive cough, with spasm of the larynx, dyspnœa, and evidence of semi-asphyxia, which passed into quiet lethargy, from which the patient gradually recovered, complaining of intense headache. The cataleptic condition lasted but an instant, the convulsions for a quarter of an hour, and the lethargy about as long. In spite of these frequent attacks, the man's general health was good, but his character was completely changed; he became constantly more irritable and violent in temper. An operation was proposed as the only rational treatment, and after some demur he consented to it. This procedure was found, however, much less simple than was expected from the impossibility of getting him quietly under the influence of chloroform, as will be explained presently. The site of the injury was about the

size of a florin, half an inch above the eyebrow, and the same from the middle line. The skin was wrinkled around and adhered to the bone. A semicircular incision was made, the base upwards, and the pericranium forced off until the edge of the fracture could be seen. The trephine was applied there, and a disc of compact bone removed in two pieces, but the gouge and mallet had to be used before the *dura mater* was exposed. This was found to be uninjured, but thickened and opaque, as if from old inflammatory mischief. The wound was washed with phenol lotion, and the flap replaced with Lister's dressings over it, and a small drainage tube inserted, and it had soundly healed in eighteen days.

Results.—Before the operation the fits recurred daily, and lasted half an hour. During the first month afterwards there was once a very slight attack with cramps in the feet, but without loss of consciousness. In the four following months there were again attacks, but extremely slight and of short duration; and, therefore, it may be reasonably expected that if the epilepsy do not disappear altogether, it will have been greatly ameliorated in all respects. But a disease which had lasted ten years must have made the habit almost inveterate; and even if the original cause were entirely removed, we might expect the profound impression made upon the brain to remain. And the thickened and altered *dura mater* might alone be sufficient to perpetuate the influence of the primary cause. The man is still under medical treatment, with the hope of eradicating these last traces. He has a draught of infusion of valerian every morning, two milligrammes of atropine during the day, and six grammes of bromide of potassium at bed-time, and this is to be continued for some time to come.

The difficulty in inducing anaesthesia has been mentioned. On November 16th he was first brought into the operating theatre, and pure chloroform carefully administered, and he quickly became insensible; but in a few minutes violent tetanic convulsions of the whole body set in, with a suffocative cough, retraction of the tongue, cyanosis, and apparently, imminent asphyxia. The tongue was seized and pulled well forward, and then, as the breathing had become tranquil, the inhalation was recommenced, but with the same results. It was suspended, the fauces well cleared, and then resumed for the third time, when, in consideration of the alarming symptoms of suffocation, and the fact that more than four ounces (130 grammes) of chloroform had been consumed, the operation was deferred until the following day. It was noticeable that the pulse was little affected, only becoming weaker and more rapid when the breathing was interrupted. As a possible preventive of these troubles ninety grains of bromide of potassium were given at bed-time, and two-thirds of a grain of morphia injected just before recommencing the operation. Another sample of chloroform was used, and of that five ounces were expended. But all in vain: the same violent convulsions came on, alternating with impending asphyxia; and it was only by seizing now and then a few minutes of calm between the two conditions, and after twice repeating the injection of morphia, that the operation was completed in an hour and a half, under what Dr. Areilza pathetically calls "*malisimas condiciones*," and he may well be congratulated on his coolness under these trying circumstances. At the end of the operation the patient was as excited as ever, in spite of having taken within twenty-six hours nine ounces of chloroform, ninety grains of bromide of potassium, and two grains of morphia! and yet he made an excellent recovery. This remarkable resistance to the ordinary action of anaesthetics—in fact, a reversal of their usual effects upon the medulla oblongata—must have been due to some subtle change in the brain, which either induced the epileptic attacks or was produced by them. Chloroform in the first case paralyses the higher intellectual centres, then the sensory, and almost simultaneously the motor, and finally, those of organic life. In this case the first stage was normal; but in the second, instead of an inhibitory influence, one of intense excitement was produced, and as we sometimes see when administering chloroform, and when the patient begins to feel its effects, there were violent convulsions in place of muscular relaxation, and the more the agent was pushed the more severe these became, until the respiratory and cardiac centres being reached, impending asphyxia compelled its withdrawal.

"If we were to accept the theory of Schroder van der Kolk as to the cause of epilepsy, strengthened by the discovery of the convulsion-centre in the protuberance of Nothnagel, the link would be obvious enough, for the epileptic convulsions set out from the same centres as are (in our patient's case) irritated by the chloroform. But this hypothesis falls to the ground before the modern view, supported by so many clinical observations—that epilepsy originates in the cortical layer of the hemispheres, and it has been shown by experiment that irritation of the surface of the frontal and ascending parietal convolutions will produce convulsions; and in this case the site of the injury was over the root of the first and second frontal folds. We may say, however, that although the cause of the epileptic attacks is to be found in the cortical layer, that the mechanism of the discharge lies in the protuberance, and we may imagine that this mechanism had been so deranged by incessant disturb-

ance that chloroform acted upon it like a fresh irritant, in place of an inhibitant; and that even now the thickened *dura mater* can provoke slight explosions, although their main cause has been entirely removed."

CASE B.—The interest of this case lies in the fact that the middle meningeal artery had been ruptured, and that an enormous clot was compressing the brain into a coma, which must soon have been fatal but for operative interference, and in showing how in traumatic apoplexy life may be occasionally saved by boldly opening the skull and removing a coagulum, without that fear of secondary hæmorrhage which generally restrains the surgeon's hand.

Martin Galbete, aged thirty-two years, received a violent blow on the head with a stick on the night of the 8th of September, 1887. He fell heavily to the ground at once, inert and insensible. A practitioner (the quiet sarcasm of *un señor médico* is lost in translation) was called, who applied leeches to the mastoid processes, blisters, and other approved remedies of the *dolce far niente* type, but the patient was ungrateful enough to remain senseless; so he was removed to the hospital five days after the infliction of the injury. He was still quite insensible, except that in recognition of loud talking he uttered some incomprehensible sounds. The expression was stupid and vacant, as if from double facial paralysis; the immovable and half-open lips allowed the constantly-secreted saliva to dribble away; and the nearly-closed lids just showed swollen blood-shot eyes, with both pupils fixed and somewhat contracted. He moved incessantly the lower limbs and the left arm; the right was passive, but not paralysed, nor was sensation abolished. Pulse seventy, temperature normal, respiration rather hurried. On the left temporal region there was a contusion, slightly swollen and cedematous, but the skin was not broken, nor could any fracture be made out. However, there was no time to be lost, so, after a few whiffs of chloroform, which tranquillized the patient, an incision was made through the whole length of the infiltrated swelling to the bone, where a fracture could be felt, which a second incision at right angles to the first revealed as an enormous depression in the inferior region of the parietal of semi-ellipsoidal form, with fissures running across the bone and into the temporal. With a gouge and cutting pliers the fragments were raised and divided, leaving an opening 3.5 inches long and 1.25 inch wide. The *dura mater* could not be seen, only a mass of blackened blood clot, tough and resistant, evidently due to rupture of the middle meningeal artery at the moment of the blow. With a flat curette and the fingers the greater part was cleared away, but the membrane could not be quite exposed without using an amount of force which would have probably torn it. Altogether, more than 100 grammes (three and a half ounces) of clot were removed, and a cavity about two inches deep remained. The clot extended far under the uninjured vault, but the point of greatest compression corresponded to the Broca's circumvolution, the third inferior frontal and the ascending parietal. The wound was washed with carbolic water, a large drainage tube inserted, the scalp sutured with wire and covered with Lister's dressings. There was an immediate change for the better, and the improvement went on so rapidly that in two days the patient had recovered full consciousness, speech, and muscular control. The wound healed by first intention, excepting in the space occupied by the drainage tube. There was no rise in temperature, and at the end of September (fifteen days after the operation) the man was discharged cured.

Before commencing the operation, the fact of past severe internal hæmorrhage was patent, and the probability that an attempt to remove the clot would lead to its return. Hence the advice of Dessault, Malgaigne, Tillau, and others, to do nothing in these cases; but then, that would be simply to leave the man to die. And, on the other hand, the delay in this instance was really advantageous, since it had lessened the chance of secondary bleeding, although it had increased the probability of cerebral mischief.

A variola em Lisboa—the Epidemic of Small-pox in Lisbon (*A Medicina Contemporanea*, Lisbon, January 15th, 1888).—In spite of the efforts of the Government and of the profession in Portugal, there is still there great popular prejudice against vaccination, a feeling which is now being combated by the establishment of an institution for the cultivation of calf-lymph, which seems to be most admirably arranged and conducted. The deaths from small-pox in Lisbon alone reached fifty-eight in the first fortnight in November, a figure which would be greatly increased if the provincial mortality were added. It had fallen, however, to fourteen in the first half of January. In Spain it has been far worse. In Madrid, during the months of November and December last, 300 persons, it is stated, died from the disease. In Spain, as in Portugal, every facility is given for gratuitous vaccination, but it has not been made compulsory. In both countries there is but one opinion on the subject amongst the profession, and generally amongst the higher classes also; but the lower, although not influenced by any organised opposition to vaccination, as in England, think more of the certain inconveniences than of the protection from an uncertain evil.

IV.—INTERNATIONAL MEDICAL CONGRESS.

GYNÆCOLOGICAL AND OBSTETRICAL NOTES.

(Communicated.)

(Continued from page 91, February, 1888).

WHY should America stand so high in gynæcological work? A difficult question to answer; but whatever explanation be offered, she does at present, as in the past, take a leading position in all that relates to the diseases of women. American women appear to require the services of a specialist pretty frequently; the demand creates a supply. One orifice, with its armature, the mouth, is especially protected and cared for in the States. Teeth are valued. American dentists lead the way. The other orifice, with all its hidden organs, must require as much care; and American women, practical and without *mauvaise honte*, find that it is well to have this orifice explored and kept in order. Is this the explanation? I need not defend this hypothesis.

Knowing the past work of America in the field of obstetrics and gynæcology, I naturally looked forward with interest to the sections devoted to these subjects at the Congress, and if you will allow I will give you my impressions, and a précis of what took place. Which section shall I take first? I think I shall ramble about from gynæcology to obstetrics, and work in a little bit from each.

The Section of Gynæcology was presided over by an accomplished gynæcologist, Dr. H. O. Marcy (Boston), and was fortunate enough in securing as secretaries Dr. G. Apostoli (Paris), Dr. S. N. Nelson (Chicago), Dr. E. W. Cushing (Boston), and Dr. Van Lawren (Hampover). In looking round the assembly I noted some well-known men from different countries; and taking particular stock of the Americans, I did not see, as regards appearance, much difference from an ordinary meeting of one of the London Societies. Amongst the papers read on the first day was one read by Nathan Bozeman, **On Artificial Draining of the Bladder, Kidney, and Uterus through the Vagina, with and without graduated pressure, in the treatment of Vesical and Persistent Fæcal Fistulæ.** According to the author, this method prevents the discomfort from incontinence of urine and improves the condition of the surfaces from operation. There was a good discussion on a paper by Dr. More Madden, of Dublin (read by Dr. Cushing), **On Sterility.**

Dr. Gordon, Maine, said cases were rare in which obstruction was too great to permit passage of semen. *Dyspareunia* is most important. It is well to look after the soil, chronic congestion destroying the soil. Dr. Graily Hewitt did more than any other to make known and correct this, and showed that it was only relieved when the uterus was placed in a proper position.

Dr. Graily Hewitt said that he applied Hodge's principles of retro-uterine support to the anterior displacements. He thought the method of dilatation merely straightened the canal; that lymph was exuded before and behind, placing the uterus in a splint, thus giving more ready egress and ingress to the fluids.

Dr. Duncan adopts dilatation but calls it canalization.

Dr. Laphort Smith, of Montreal, says the other side of the house should not be neglected; that often the woman is persecuted in various ways, when it is found subsequently that there is not a spermatozoid in the semen.

Dr. Nelson, of Chicago, says the mucous membrane must be capable of normal congestion in order that the ovum can secure a lodging place.

Dr. Garnet read for Dr. Bigelow (Boston) a paper on **Conservative Gynæcology.**—It was a general plea for more conservative measures, and the author seemed to favour the idea that there were too many operations performed. The treatment of myoma was the subject of several communications, and the section was very much interested in Apostoli's paper on **Faradisation in Gynæcology.**—His views were generally supported.

Dr. Franklin Martin read a paper on **Electrolysis in Uterine Myoma**, in which he spoke of the value of strong currents and exact dosage.

1. The local effects of the poles produce a kind of cauterization, acid or alkaline, according to the pole.

2. Atrophic effect. The results of a peculiar irritation upon the trophic nerves.

3. Electrolytic action.

4. Anti-neuralgic effect.

He does not use electro-puncture, believing it dangerous. He showed a number of ingenious electrodes, and recommends a dynamo instead of the cell battery. In conclusion, he said its advantages were:

1. It is entirely free from danger.

2. It is absolutely painless.

3. It invariably checks excessive hæmorrhage.

4. It rapidly reduces the size of the tumours.

5. It stops neuralgic pains.

6. It is a system of treatment of fibroid tumours by electricity based upon principles which make exact dosage possible.

I think one of the most characteristic papers of the meeting was read by Dr. Dunlap, who may be regarded as the successor of McDowell, and who brought us back to the early days of ovariectomy, when he described his early operations performed under great difficulties. It seemed almost incredible to think that the report of one of his early cases was refused publication in one of the medical journals of the time. Another pioneer was present, in the person of Dr. Kimball (Lowell, Mass.), who narrated his experiences, and told of the difficulties he had forty years ago. In one case he had invited a number of assistant surgeons to see the operation, and help him, but as he had to proceed slowly, owing to adhesions, when he looked round for his assistants, all had departed save one. We can hardly imagine at the present day the opposition there was to ovariectomy at its inception, but we may form some slight idea of it, if we pursue some of the literature connected with some of the modern operations for the relief of the unfortunate women suffering from diseased ovaries and tubes. Speaking of operations, I may here allude to a discussion which took place in the section of obstetrics on a paper by Professor Wathen **On Cæsarean Section** (published in the *Provincial Medical Journal* in full, November, 1887, page 487).

Prof. A. R. Simpson, of Edinburgh, opened the discussion. He did not think that the time had yet come for the general practitioner to throw away the instruments for craniotomy, which he had become accustomed to. In Edinburgh the cases requiring breaking up of the head have, in recent years, become very unusual. If the condition of the woman before labour can be carefully studied, and a favourable opportunity for the operation selected, Sænger's modified operation certainly promises the best result. Porro's operation is indicated if there is grave disease of the uterus, which can perhaps be cured at the same time.

Dr. Martin, (Berlin) said that he had seen many operations according to the old method. Sænger's modification enables us to form a new judgment concerning the operation. It is now a safe procedure. Not every practitioner, however, can do the operation in the backwoods without preparation and without assistance. Moreover an effort should be made to deliver the child *per vias naturales*, if the pelvis is not too greatly contracted, before resorting to laparotomy. If there is no hope of delivering the child alive through the pelvis, there is at present a disposition to do either the modified Cæsarean or Porro's operation. Both are justifiable. The former holds out hope of perfect recovery, the latter removes hope of subsequent pregnancy. In cases of tumour—fibroid or epithelial—either Porro's operation or total extirpation of the uterus may be indicated.

Dr. Johnston (Washington) desired to emphasize the remarks already made, that the great causes of failure were delay in beginning the operation, and the making trial of other operations in the hope of avoiding an abdominal section, so that the patient succumbed as a result of former unsuccessful attempts at delivery, rather than of the last operation. He reported the case of a woman in whom he had performed the Cæsarean section after the woman had been in labour three days. Unsuccessful attempts to deliver with the forceps, as well as by turning and craniotomy, during which she had been under ether four hours, had been made. During the operation the uterus was found to be badly bruised. The woman died on the tenth day of an abscess on the left side, which had ruptured into the peritoneal cavity. Perhaps a Porro operation might have saved her. It is necessary to increase our knowledge of pelvimetry. It should be remembered that most of the foreign statistics relate to operations done by men who were already extremely skilful laparotomists.

Dr. Ball-Headly, of Melbourne, Australia, said that Dr. Greenhaugh, of London, was perhaps the first who had performed Cæsarean section in a case of epithelioma. Total extirpation of the uterus is often preferable in these cases at the present time. Twenty years ago he knew a German practitioner who lived in a region where very many women had soft bones, and who did Cæsarean section very frequently (and sometimes repeatedly on the same woman), and with very few deaths. He himself had done a Porro operation upon a dwarf with an entero-posterior diameter of one inch. The operation was exceedingly easy, having been completed in twenty-five minutes. It was not pleasant to be obliged to operate if the tissues were bruised.

Dr. J. A. Doleris, of Paris, agreed with preceding speakers, and discussed the technique of different operations.

Prof. W. W. Jaggard spoke of the relative indications for craniotomy and laparotomy. He argued that the former did not require extraordinary skill, was comparatively safe, and was preferred by the mother. He thought the present interest in delivery by laparotomy was largely based upon sentimentality, or, to call it by a more pleasant name, upon scientific interest. The life of these children is not of great value.

Prof. Lusk controverted these propositions. When the antero-posterior diameter is under three inches seven centimeters, craniotomy is not, as a rule, safe or simple. In contracted pelvis the Cæsarean section is ordinarily no more dangerous than craniotomy. The children do not, as a rule, die under twelve days.

Back to gynecology again for a paper by Professor Martin on **Vaginal Total Extirpation of the Uterus for Cancer**.—Professor Martin asked: (1) Is this operation practicable with such success, that it promises good results in the hands of others than a few specially successful operators? (2) Does it give permanent results superior to any other treatment of cancer employed at present?

Meagre and isolated reports of this operation are only to be found in English and German papers, though it has obtained recognition in Germany. The results have improved:

1881.	Olhausen collected 41 cases, with 29 per cent. mortality.
1883.	Sänger " 133 " 28 " "
1884.	Engström " 157 " 29 " "
1886.	Hegar " 257 " 23 " "

Up to 1886 the following total extirpations have been performed for carcinoma:

Fritsch	60 cases; 7 deaths.
Leopold	42 " 4 "
Olhausen	47 " 12 "
Schröder	74 " 12 "
Stande	22 " 1 "
Martin ..	66 " 11 "

311 47

A mortality of 15.1 per cent. Are we not justified in hoping for a lower mortality in the future, with improved methods and experience? Yes. This operation ranks well with the other methods. Dr. Martin's recommendation is clear and emphatic: "I recommend," he said, "vaginal extirpation of the uterus as the operation and as the means, which we ought to apply in case of cancer of the uterus, as long as the disease is limited to the uterus itself."

So much for one side of the question. Dr. Reeves Jackson (Chicago) presented another aspect, and taking Dr. Martin's figures, he draws a picture which might well make surgeons hesitate before performing this operation—viz., extirpation of the uterus. "I have for a long time believed that statistics upon this subject are unreliable, and that if the whole truth were known, the results of the operation would be more unreliable than they now appear. In order to test this opinion I have recently obtained the histories of seventeen cases of vaginal hysterectomy for cancer in Chicago. Of seventeen cases nine were promptly fatal; one lived six months, one two years, and one three years and eight months. The remaining five are still living, the operations having been done seven, five, four months, and one five weeks ago. Of the seventeen cases, with a mortality of fifty per cent., two only have been published."

In reply to the two questions asked by Dr. Martin, he replied: Dr. Martin does not hesitate to answer his first question in the affirmative, and instead of giving the results of the work of the "others" in support of his position, he only furnishes those of the especially successful operators of Europe, a method of argumentation calculated to mislead, because based upon only a partial presentation of the facts. This, at least, seems clear. If the 311 cases given in Dr. Martin's table show an immediate mortality of only 15.1 per cent., it follows that the mortality of the "others," which has been estimated at about twenty-eight per cent., must be very much higher than has been supposed. Thus, Dr. Martin's statement of data seems to contradict the correctness of his conclusion. In reply to Dr. Martin's question, "Is there any other method of treating cancer which, with so small a mortality, can show equally good results?" I answer unequivocally in the affirmative; Dr. Martin believes otherwise. I beg to offer the following conclusions: (1) Cancer of the uterus is originally a local disease, and is curable by complete removal. (2) Any operation for cancer which does not completely remove the disease will be followed by recurrence. (3) The extent of cancerous disease originating in any part of the uterus cannot be known prior to or during operation, hence no operative procedure can afford a guarantee of complete removal or of immunity from recurrence. (4) In the radical treatment of uterine cancer the most favourable results, both immediate and remote, have been obtained by the amputation of the diseased portion by means of the galvanocautery, the hot iron, and the knife. (5) Kolpo-hysterectomy is more dangerous, and has given worse results than any other mode of treatment. It has destroyed, and has not saved life.

It is an injurious, and not a useful operation; it is more rapidly destructive of life than the disease against which it has been used. Hence it should be condemned as unjustifiable. There was a good

discussion on these two papers. Dr. Dirner, Buda-Pesth, said: Humanity commands us to execute total extirpation of the uterus, but only in cases where we are sure of being able to remove, as far as possible, all morbid matter, and when we have at our disposal the experience and skill necessary for the operation. Patients with cancer are shipwrecked and condemned to death. Such shipwrecked lives may be saved. Those who survive after the operation in some cases enjoy life for a short time, others have their lives preserved. Should we save but even one life we do well. Dr. Palmer Dudley, New York, joined in the discussion, and pointed out that in the sixty-six he had reported, there had been thirty-three different operators, with a mortality of forty-four per cent.; whilst, in sixty-six cases reported by Dr. Martin, done by himself, there had been only eleven deaths. American surgeons have not had a fair trial, but he felt certain that, with increased skill and experience, they would be able to show results as good as those of Dr. Martin. Dr. Graily Hewitt said they were indebted to Dr. Martin and his colleagues for their work and for their advances in the operation. A few years ago, at the Obstetrical Society of London, he was the only speaker who did not condemn the operation.

(To be continued.)

V.—DISEASES OF WOMEN AND CHILDREN.

Laparo-Salpingotomy done in 1784 in Russia.—M. Schlisinger in the *Rev. de la Soc. d'Obst. et de Gynec.*, No. 3, cites a case of laparo-salpingotomy done by Seydel in 1784 in the manner which is now known under the name of Volkmann. The patient was a woman of forty-two, a multipara, who had a miscarriage two years before. In the summer of 1783 she presented herself with a round hard tumour in hypogastric region towards the right side. It had the appearance of the gravid uterus at the third month, and as time went on it kept increasing in size. At the menstrual epoch it was the seat of sharp, shooting pains. At last it attained the size of a two-year-old child's head and became more mobile. Vaginal examination showed the tumour to be attached to the uterus by a short, hard pedicle. The patient was prepared for operation by baths and the administration of gentle purgatives and Peruvian bark, while just before the operation she was given some laudanum with syrup of white poppies and Hoffman's anodyne. The operation was performed February 21st, 1784, at Sarepta in Astraken. An incision was made, right over the centre of the tumour, extending from the umbilicus to the right inguinal ring and the peritoneum was opened with a curved, blunt-point bistoury guided by the finger of the operator. Three veins were ligated. The intestines were protected by towels soaked in tepid milk. The tumour presented itself and was opened giving exit to at least a pound and a half of chocolate-coloured, odourless, thick, sticky liquid. The operator then perceived that it was not a tumour of the ovary but of the tube. After evacuation of the sac the operator poured into it some decoction of Peruvian bark, some solution of myrrh, and then introduced a coil of lint steeped in the "balm of Arceus." To prevent adhesions between the peritoneum and intestines they were separated by strips of muslin dipped in oil of roses. The wound was dressed with linen and a plaster; later it was sutured. During the first few days the surgeon evacuated the fluid by means of a silver tube; but later, as the discharge slackened, the operator sucked out with his mouth a thick, fetid liquid. There was some fever for seven days, but none at the end of the fortnight, when the discharge had ceased, the wound healed and the patient was well. Two years later she still enjoyed perfect health. [Translated for the *Gaz. Hebdomadaire des Sci. Med. de Montpellier*, January 7th, 1888, by Mme. Al. Tkatcheff—*Med. Analectic*, February, 1888.]

Acid Lactic in the Treatment of Ulcer Exedens of the Vulva (*Gazette de Gynecologie*, p. 46).—Dr. Cheron praises the effects of lactic acid in the above condition, scarification, sulphuret of carbon, and iodoformed carbon. The resolvent action of the sulphuride of carbon is marked on the indurations. Dr. Cheron also uses—

Acid lactic..... } Equal
Distilled water..... } parts.

Applied locally, and he speaks well of its effects.

Painful Dyspepsia in Uterine Affections (*Ibid.*).—Dr. Menière frequently employs the following mixture for the above; the action, he says, is rapid:

Bromide of sodium..... 4 grammes.
Tinct. aconite..... 1 gramme.
Tinct. nux vomica..... 15 drops.
Chloro-hydrate of morphine..... 0.03 centigrammes.
Simple syrup..... 15 grammes.
Elixir of garus..... 20 "
Distilled water..... 60 "

Take a desert-spoonful before each repast.

Atony and Constipation in Uterine Affections (*Ibid.*).—The digestive apparatus is frequently troubled when uterine disturbance is present. Bardel proposes the following laxative stomach mixture :

Fluid extract of cascara sagrada	20 grains
Tinct. nux vomica	2 "
Hydrolate of laurocerase	15 "
Distilled water	100 "

Mix three or four desert-spoonfuls daily.

Treatment of Vegetations in Pregnant Women.—The physician is frequently consulted by pregnant women, who complain of having what they called little excrescences on their external genital parts. These vegetations have no relation with syphilis. They are generally discrete, and without inconvenience, but sometimes they become confluent, and of large size, and owing to the odour are unpleasant. Almost all accoucheurs advise not to touch them, as they generally disappear after confinement; or most advise interference when they assume considerable proportions. M. Decoster is of opinion that they ought to be energetically treated before labour, as he says they may give rise to hæmorrhage, may become the seat of micro-organisms, and may give rise to lymphangitis, septicæmia, and peritonitis. M. Decoster recommends cauterisation, with nitrate of silver. We agree with Dr. le Page, that it is best not treat these vegetations unless they are of considerable size, or cause grave inconvenience. This is the opinion of Tarnier, Cullerier, and Budin.

Water as an Antiseptic.—Dr. Menière says the accidents occasioned by phenic acid, iodoform, and sublimate are so frequent, and so well known, that the surgeon had better use simple water after filtration and ebullition, at 100 or even 120. It is the best aseptic we have at our disposal. For two years he has used boiled water for hypodermic injections of hydro-chlorate of morphine. We believe that the custom set in England by Mr. Tait of using water will be followed by most gynæcologists.

Hybrid Gonorrhæal Affection in Women (*Annales de Gynécologie*, page 371).—Bumm (Wurzburg) understands by hybrid infection the introduction of two kinds of organisms. The habitual process is as follows: One of the species creates in the organ on which it acts a morbid state, and then on this prepared ground the second species takes up its domicile. Thus a lung attacked by pneumonia is very accessible to the bacillus tuberculosis. A similar process takes place in gonorrhæal infection in women. Micro-organisms of suppuration come subsequent to the gonococcus of gonorrhœa.

Tait's Operation for Perineorrhaphy.—At the meeting of the German Physicians and Naturalists at Weisbaden, 1887, Sängser said, he had recourse seventeen times to this operation: seven times for prolapse, three times for complete rupture, seven times for incomplete, with excellent results. Sängser said that the simplicity and rapidity of the operation recommended it, and that the method represented a grand progress in perineoplastic operations.

VI.—PUBLIC HEALTH.

Report on the Cholera of 1883 (Translated from the *Muqtataf*, February, 1888).—When cholera broke out in Egypt in 1883, several European Commissions were sent by their governments to investigate as to the nature of the epidemic on Egyptian soil. The German Commission, headed by the celebrated Dr. Robert Koch (well known to our readers by his discovery of the bacillus of tubercle, and of the comma bacillus of cholera), was among the most prominent. It left Berlin on August 16th, 1883, and arrived at Alexandria on the 24th of the same month, after visiting Port Said on the previous day. In Alexandria preparations were soon made for carrying out a thorough investigation, and expeditions were afterwards made to Damietta (where the epidemic first broke out), Mansoura, Tanta, Cairo, and other places. Having completed its work so far as Egypt was concerned, the Commission went to India, where further investigations were made; and after returning to Berlin, it prepared the elaborate and exhaustive report which was published, with many plates and maps, at the expense of the German Government.

In perusing this report, the reader is struck by the ingenious way in which the narrative of a journey, and the description of views of towns and countries, are so well and easily connected with deep research and severe criticism, in a dry and uninteresting subject to the general reader. Our space is very limited, so that we can only give the bare outlines of the report in as far as it concerns Egypt, leaving unnoticed the other not less valuable parts of the report on Quarantine in Egypt and the Red Sea, Cholera in the Hejaz, and Cholera in India. A good description of Damietta, and of its sanitary state previous to the outbreak of cholera, is given, and the beginning of the epidemic there is described as far as it could be traced. The different views on the

origin of cholera in Egypt are then brought forward, and the reports of Dr. Shaffi, Dr. Terrari, Dr. Dutrieux Bey, and Surgeon-General Hunter (who was then sent by the English Government) are examined, and the untenability of their views—views that are already well known to our readers—is lucidly shown. A table taken from Dr. Grant Bey's report on the cholera of 1883 (*British Medical Journal*, February, 1884) is added to corroborate the view that Asiatic cholera is not endemic in Egypt.

In treating of cholera in Cairo, the report shows clearly how little care was taken to keep the potable water of the town free from impurities and germs of disease. Much has been taken from the reports of Dr. Ahmed Bey Hamdi and Dr. Wild in support of that (to us) undoubted fact. In Alexandria, as well as in other Egyptian towns, the dirty state of the roads and dwellings, as well as the bad sanitation, are not lost sight of; and the zeal of some doctors—as Dr. Kartulis—to facilitate scientific research is highly spoken of. A chapter is devoted to the comparison of the epidemic of 1883 with former epidemics in Egypt, and especially with that of 1865. There are altogether six epidemics¹ of cholera on record in Egypt, all of which broke out either in June or July of the years 1831, 1838, 1850, 1855, 1865, and 1883, the last following after eighteen years. Among the most valuable contents of this report is a chapter on the Nature and Cultivation of the Cholera Bacillus, of which we may give an extract by and by.

This report of the research of one of the greatest authorities on the Asiatic cholera—which refers to so many Egyptian doctors, opposing the views of some, and upholding the views of others—cannot fail, we think, to raise as much discussion among our doctors as it will do among European doctors. Dr. Grant Bey, who so zealously upholds the view here that cholera is not endemic in Egypt, and who, some two years ago, challenged his opponents to a discussion on the subject in a severe criticism of Drs. Shaffi's and Ferran's reports, and of Dr. Hassan Pasha Mahmoud's article on Cholera, as was then published in this journal, may now expect to find his challenge—hitherto not responded to—accepted by the opposing host that ought now, if ever, to send out its champion to meet him in the field of conflict. Surgeon-General Hunter's views are terribly shattered in this report; and Dr. Mackey, of Alexandria, who is there represented as "chiming in" with these views, can hardly be expected to "chime" in silence now. The question is not settled yet, as the other party has, no doubt, still somewhat to say in support of its views.

The Spirit of the Societies.

LIVERPOOL MEDICAL INSTITUTE, January 19th, 1888, Dr. WILLIAM CARTER (President) in the chair. **Discussion on the Routine Excision of Joints.**—Mr. ROBERT JONES introducing the subject said that it was necessary to protest against a recent revival of excision in early joint disease, and agreed that the resort to early operative measures was proof that the correct principles of treatment were not understood. He stated that it was of immense importance to detect early disease, and to treat in such a manner that if it became serious no change of principle would be of use. There should be no difference in the theory of treatment in the case of a knuckle to that in the case of the hip. Suitable mechanical appliances should be fixed, so as to secure the utmost rest without compressing the diseased areas. Mr. Thomas's appliances best secured these ends. Mr. Robert Jones took as a sample the case of a knee which was supposed to be inflamed. Having secured it in a splint, he considered the effusion. If sensitive, he recommended an ice bag so slung as to give rise to no appreciable weight. He aspirated if, in a spontaneous collection, no diminution occurred in ten days. In the case of hæmorrhage, he advocated early aspiration to be repeated when necessary. If effusion, no matter what its character should give rise to, acute pain, or fever, aspirations should be insisted on. Two points were to be regarded in aspiration. (1) Not to operate until the knee was fixed in splint. (2) Not to use too fine a bored needle, lest prodding should be encouraged when the surgeon failed to get pus. It was not uncommon for him to aspirate once a week in certain cases for lengthened periods. If pus were thick or cheesy, or if constitutional symptoms arose, incision should be discussed. Personally he did not employ Listerism, as the lengthened time abscess took to heal only convinced him of the value of the simplest dressings. He thought drainage of more importance, and to see to the opening being in the most dependent spot. He strongly condemned transfixing the joint with drainage tubes. Incision should at once follow and check the ramification of abscess cavity. It was often necessary to wait long

¹ The suppressed report of the British Consul gives a seventh epidemic of cholera in 1837.

and patiently for improvement, and not to be deterred by retrogressive tendencies on the part of the joint. The vast majority got well if waiting were sufficiently long. Some recovered maimed, and a large proportion of even the worst cases finally attained movable joints. With the disappearance of pain and fever, let them don a walking splint so constructed as to allow progression and disallow articular motion. Country air worked wonders on their constitutions. He had many such patients with discharging sinuses living in country places who did not need to be seen for months at a time. The joint should be imprisoned long after the appearance of disease has gone. The knowledge whereby a joint can be affirmed recovered was very necessary, and was only in very vague terms referred to in text books, and that not correctly. It were as necessary to detect recovery as to detect disease, and the want of this knowledge accounted for the frequent relapses. Mr. Thomas' theory of the test of recovery was the most reliable, and was founded on the means of detecting early disease. The law might be roughly laid down that a joint was cured of disease when the range of movement did not diminish by use. Mr. Jones then dealt at length on the details of this method, and its practical applications. He further alluded to those cases which sometimes ran an erratic course, mainly in patients over sixteen. He urged that they were rare, and that the joints seemed too well to account for the symptoms on any but septicæmic grounds, and gave reasons for deprecating their excision. One great cause of the frequent resort to excision was founded on the want of a practical acquaintance with the principles of rest. The term differed in meaning almost every time used; its quality should be stated. Its quantitative estimation was also necessary to its definition. Another cause of failure was due to inattention to the mechanical details of splintage. In Liverpool and elsewhere very few really understood the proper application of the posterior hip splint, so that its full benefits were rarely attained. A splint was no more automatic than a violin. Another fallacy was the fear of ankylosis from long confinement. Mr. Jones removed a hip splint before the meeting, from a boy who had been confined four years in it, and who, up to that moment, had not had his splint removed. Motion in the hip was, in spite of this, quite good. "Passive motions" he also condemned it as utterly alien to the principles of rest. The extension of joints was even worse. The main clinical argument against the school was the frequency with which they advocated operation. Extension had been proved to induce disease in the strong and resisting tissues of healthy joints; how, therefore, could articulation saddened by disease be benefited. An inflamed capsule could not be improved by stretching. In the case of the hip in the early stages, extension could only induce pressure upon the lower and inner aspect of acetabulum, and adjoining surface of femur. Muscular control was easier and safer attained by extension. The speaker accounted for the relief of pain which at times attended excision; he considered the advice tendered by Mr. Wright, of Manchester, to excise as soon as abscess was detected, as extremely retrogressive. If followed, it would relegate to mutilation and deformity, a large number of curable cases. The little baby, for instance, exhibited that evening with perfect motion at the hip, would be destined, had his advice been followed, to limp for life. So would fifteen or sixteen of the other cases. The operator could claim no advantage over him who relied on rest in its full sense. The former did not cure but obliterated joints, whereas, the latter cured a number which became totally free from defect, others were partially defective, and his worse cases compared favourably with the operator's best. Howard Marsh and Mitchell Banks had pointed out the infrequency of operation among the well-to-do, and Mr. Jones argued that endeavour should be made to place on equal footing hospital patients. When cases were shown to advocates of excision which had recovered in spite of the worst disease, they argued still in favour of operation, because of time saved. They could not deny superiority of result to those who could afford to wait, but resorted to operation as an expedient of hurry. The same argument would relegate a one-legged artisan to a wooden stump, instead of an expensive artificial limb, and did not argue against treatment by rest, but against his good fortune. In the case of children there could be no excuse for this argument. Mr. Jones then argued at length to prove that the time saved was very trivial unless almost healthy joints were excised, although the treatment of those who practised rest was deficient in many elements which he, Mr. Jones, thought essential to the correct appreciation of the term. He added that the improved market value of a man properly cured would outweigh the defect of length of time. To this should also be added the direct mortality from operation and the frequent flail sequelæ. Some surgeons excised because of the pathological conditions they diagnosed. They seem unaware that recoveries could take place where rupture of capsule, abscess of joint, synovial thickenings and ulceration of cartilage, had taken place. The cases shown that evening with numerous sinuses and movable joints should reassure them. The fear of diathesis, more especially the tubercular, alarmed others. Either the term was much too fre-

quently applied, or the disease was curable. He referred to the discussion on tubercular peritonitis held at the Clinical Society on October 28th. He maintained that all surgeons of experience would be able to refer to old cases of strumous or tubercular disease where patients had recovered unassisted by art, and had appeared at hospital for the rectification of deformities. Some of the cured cases exhibited that evening betrayed typical strumous characters. He would not include under the term excision those cases of incision into hip for the removal of necrosed bone, or loose bone; such operations on surgical grounds were urgent. After summing up in favour of saving joints in preference to excising them, Mr. Jones urged that it was more important to reclaim those tissues encroached upon by disease than to advocate their sacrifice.

Mr. ROBERT JONES and Mr. THOMAS showed, amongst other cases, the following in illustration of the paper:

Case 1.—J. Q., æt. six; suppurative arthritis of knee, three years in splint. Two years ago abscess of knee opened on inner side. Rest uninterrupted; movement of joint increasing.

Case 2.—Suppurative arthritis of Knee. H. W., æt. sixteen. Duration of disease two years. Suppuration of joint. Aspirated seventeen times. Joint also opened. Shortening quarter of an inch. Good range of motion.

Case 3.—Suppurative arthritis—amyloid disease. C. B., æt. twelve. Duration of disease nine years. In splint for eight years without interruption. Aspiration thirty or forty times. Six sinuses into joint. Half-inch shortening. Very good motion in joint.

Case 4.—Suppurative arthritis of knee. Two sinuses into knee. Total duration of disease nine months. Deformed and ankylosed during disease. Good motion now.

Case 5.—Suppurative arthritis of ankle. Twelve months in splint. Two sinuses. Prolonged pyrexia. Free motion in joint.

Case 6.—Suppurative arthritis of hip joint with fifteen sinuses leading into hip-joint. Kidney diseased for two years. In splint for ten years. Patient twenty-five years old. Can now walk long distances. No deformity. Shortening three-quarters of an inch.

Case 7.—Suppurative disease of ankle. C. B., æt. eight. Two sinuses. In splint six years. Movable ankle.

Case 8.—Suppurative arthritis of elbow. Two sinuses. Patient under treatment for eighteen months, during which time albuminuria was present and liver enlarged. Recovery with free motion.

Case 9.—Suppurative arthritis of hip with lordosis and tilted pelvis. Eighteen months under treatment. Two incisions made. Correction of deformity. Shortening scarcely half an inch, although the apparent shortening when first seen was three inches. Free motion in joint.

Case 10.—Arthritis of hip. Splint taken off at meeting for first time after four years to show that long-continued rest did not result in ankylosis. Motion free.

Case 11.—Suppurative arthritis of hip. Three abscesses into joint. Lardaceous disease and dropsy for twelve months. Complete recovery, with three-quarters of an inch shortening.

Case 12.—Suppurative arthritis of knee. Knee splint five months. VERY SLIGHT movement, which is increasing.

Case 13.—Suppurative hip disease in a baby cured after eighteen months treatment, where only one aspiration proved necessary. Motion free.

Mr. JONES showed several other cases of a similar kind in proof of his assertion at a previous discussion, that under the proper application of prolonged rest joints recovered their functions in spite of extensive suppuration.

Dr. ALEXANDER said he deprecated routine treatment of any kind, and he certainly deprecated the routine treatment of joints. The advocates of rest, however, sometimes went too far, and cases were lost through their unwillingness to operate. He disagreed with the early "excisionists," and thought excision should only be performed when dead bone required to be removed. The great majority of diseased joints could, however, be cured by rest, especially rest commenced early and long continued. In spite of rest a number of cases drafted into hospital for operation, and often when admitted the disease would only admit of amputation. By earlier operation the limb might have been saved. He did not think aspiration was always necessary in hæmorrhosis.

Prof. RUSHTON PARKER would not attempt to criticize severally the many points taken up by Mr. Jones, but in general terms agreed with most of the views he expressed. There was no doubt that among surgeons who had carefully devoted themselves to the improvement of their mechanical treatment of joint affections, the necessity of excision had greatly declined in frequency. Not that excision could ever be totally abolished, but they had certainly come to be less relied on in Liverpool and London. By the force of example, too, the number of such operations had been further diminished, just as in a former time the same influence had led to their multiplication.

Mr. PUZEY congratulated Mr. Robert Jones on having been able to collect such a large number of patients to illustrate his views. The cases showed the result of great patience and perseverance on the part of the surgeon, and of great patience and faith on the part of the patients, many of whom bore abundant marks of the trials through which they had passed. There appeared one serious objection to this expectant treatment in the case of the working classes, and that is the length of time over which it extends—two or three of the cases had required seven years, one or two nine years, and one over ten years for cure. Surely in such cases excision would be preferable. As an example of his meaning, Mr. PuzeY mentioned the case of a boiler-maker who had been off work for three years under expectant treatment for elbow-joint disease; when he came to the Northern Hospital Mr. PuzeY excised the joint, and the man returned to his old work in six months time with a strong and perfectly-movable elbow. With young people and children, of course, time is not such an object, but even in their case serious risk is incurred from prolonged and exhausting suppuration, with its frequent result of visceral mischief. The cases shown that night were most interesting, and in themselves remarkable successes; but the most important point was what proportion did they bear to the non-successes; to the cases which had ended in excision, or amputation, or death? The experience of surgeons to general hospitals and parish infirmaries was that too prolonged reliance on the expectant treatment of joint disease ended too frequently in amputation or in death, either directly from the joint mischief, or indirectly from induced visceral disease.

Mr. BARK congratulated Mr. Robert Jones on his paper. He remembered the epidemic of excisions about the year 1874 or 1875 so feelingly referred to by Mr. Rushton Parker, and had a vivid recollection of the exhaustive suppuration, the long and tedious character of the healing process, the flail-like movement of the limb after healing took place, and the numerous secondary operations in the form of amputations. He had an experience of more than twelve years in the treatment by rest and proper drainage, so ably advocated by Mr. Jones, and had never been disappointed, or ever felt a desire to return to excision. Mr. PuzeY mentioned a very successful case of elbow-joint excision as an unanswerable argument in favour of his side of the question; but all surgeons knew that this joint was the most favourable for the operation. He would have liked Mr. PuzeY, or the other gentlemen who vaunted excision, to have produced a few cases of hip or knee-joints as favourable in duration and ending as his elbow case. He maintained that Mr. Robert Jones had proved, theoretically and practically, what he intended—viz., "That diseased joints may be treated by prolonged rest and drainage, even after extensive suppuration, without impairing the mobility of the joint."

Mr. GEORGE HAMILTON regretted not having reached in time to see Mr. Robert Jones's cases, but he thought that generally excisions gave better results than rest. He had witnessed some excisions which had been performed very early, where good movement resulted. He, Mr. Hamilton, knew of a case of hip disease in his neighbourhood, where, after treatment by complete rest, and that by one who was well acquainted with the method, the child now wore three inches under the sound foot. He thought that was worse than excision. He felt sure that if Mr. Jones knew the end of his cases he would find some of them gravitated to the Northern Hospital. He thought Mr. Robert Jones would one day begin to excise.

Mr. RHINALLT PUGHE believed in the usefulness of excision. He thought there was no merit in curing joints if the patients ultimately died of amyloid disease.

After a few remarks from Dr. BARR, who suggested a verbal alteration in the paper, Dr. ARCHER asked what became of patients who were the subjects of amyloid disease. Did they recover, or ultimately die of phthisis?

The PRESIDENT expressed himself much interested in the discussion, and asked Mr. Jones whether he noticed any diminution in the size of the amyloid livers during treatment. He related a case of Mr. Paul's where, after an operation for suppurative disease, the amyloid disease disappeared. It would be very interesting to learn whether Mr. Jones's amyloid cases fully recovered.

Mr. H. O. THOMAS, while agreeing with some of the opinions expressed by previous speakers, drew attention that in neither medicine nor surgery have we infallible forms of treatment; whether joints be treated by the utmost attainable rest, excised, or amputated, there must be a mortality. He further maintained that if our principles were reformed the mechanical treatment of joints would also improve; and that no improvement in the construction of instruments will avail until the theory of treatment is set right. The mortality attendant upon attempts to conserve diseased joints will not diminish so long as we continue so heedless in searching after correct principles. He contended

also that the best excision never equalled a conserved though ankylosed joint. Mr. Hamilton referred to a case of conserved hip-joint in which there was shortening of three inches. The case had been under treatment some years ago, when the patient was only four or five years of age, and had recovered with ankylosis. There was no trace of lardosis or angular deformity. As in excisions, the shortening is relative to the age of the patient, and to the time at which the operation is performed; for if the patient is a very young one the shortening when she arrives at the adult period is much greater than would remain after excision in adult life. The history of the case Mr. Hamilton alluded to is, that some years ago, the patient was treated for slight hip-joint inflammation, and during which treatment a practitioner of medicine casually visited the patient's home, and also examined the case, giving at the same time the emphatic opinion that the child was not, and had never suffered from hip-joint inflammation. This diagnosis induced the parents to suspend all treatment, with the result that the hip-joint suppurated, sinuses formed, and the kidneys became affected; still it ultimately recovered with a useful limb. It is true with the defect of ankylosis and shortening, yet much more to be preferred to the defect known as flail, and the greater shortening to be observed after some excisions. In his own practice, in principle his treatment of joint disease was characterised as the indirect method. All retention being applied to sound parts, just as in medicine, sometimes the beneficial action of the remedy follows from its effects upon parts healthy, affecting only indirectly the diseased area. Joints suffering from traumatism, the speaker admitted, were very tolerant of the direct method of retention. Referring to Mr. Bark's early experience of excision, he also had a vivid recollection of the fearful epidemic for excising, that lasted from about 1857 to 1877, and could exhibit, if required, flail hips and elbows, and hips still discharging pus. He met with one case of hip flail after a recent excision. It was an excellent case as regards sound recovery, but the lower extremity remained attached to the trunk by what might be fairly termed a pedicle, permitting of such liberty that the subject could tickle his ear with his big toe, and that only when the hand was used as a guide.

Mr. ROBERT JONES, in reply, said that many cases of amyloid disease recovered during treatment, and that five or six cases had been shown that evening. He added that vexatious and irritating treatment would be likely to induce the amyloid condition. Mr. PuzeY had chosen the cases that had taken the longest time in order to disparage the treatment by rest. Mr. Jones, however, had chosen samples of such cases in order to show the motion that ultimately accrued in cases which text-books would denounce as disorganised joints. He had, however, shown suppurative joints cured in nine months. Mr. PuzeY, however, had not referred to the movable joints obtained by rest and precluded by excision. He thought it was too much, after upwards of twenty cases had been shown, all of them recovered from the worst type of disease, to be asked what became of the others. It might be equally asked of Mr. PuzeY's excisions. Nor did he think Mr. Hamilton's reference to the Northern Hospital likely to assist in the discussion. It was far better not to compare the merits or demerits of individuals or institutions. Most of the cases shown that evening had had previous treatment elsewhere; but the patients had been specially told not to refer to it. After answering various speakers, he hoped that the cases shown that evening would be a plea on behalf of joints threatened with excision, and he thought that members would agree with him that long confinement and extensive suppuration of joints did not preclude recovery with good motion.

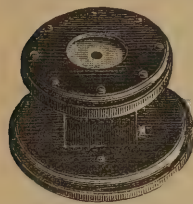

* * * * *

OBSTETRICAL SOCIETY OF LONDON, February 1st, 1888. On the effect of Ergot on the Involution of the Uterus.—There is much diversity of opinion on the value of ergot in labour, some authors going so far as to absolutely condemn its use. Drs. HERMAN and C. O. FOWLER, in a paper read before the above Society, brought forward a series of observations novel to a certain extent, and opening out a new field of enquiry. Fifty-eight patients were treated with an ergot mixture for a fortnight after labour. Sixty-eight had a single dose after labour, and no more. The uterus diminished more rapidly in size in the first series than in the second. The ergot did not seem to have any effect on the lochial discharge.—Dr. BOYAL gave ergot mixture to every alternate patient, and he concluded that the ergot had not appreciable effect on the lochia; but it tended to prevent the formation of clots, to hasten their expulsion, and to diminish the after-pains.—Dr. DAKIN, in his observations, did not support the view taken by the authors. With reference to the retention of clots and the recurrence of after-pains, he found that out of 92 cases where ergot had been given three days, 51 had after-pains and 22 passed clots. Out of 105 cases where only one dose of ergot was given, 64 had after-pains and 41 passed clots. Dr. Dakin pointed out many sources of fallacy in observations of this kind.

Surgical Aids and Appliances.

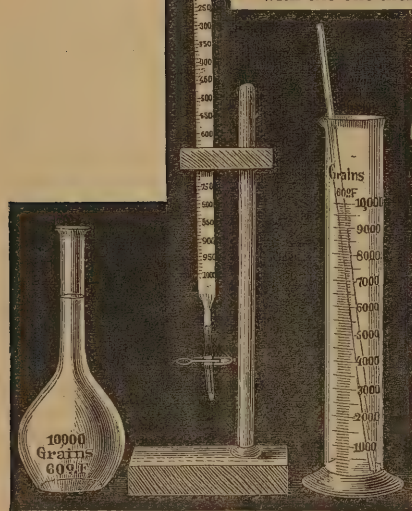

90.—THE "SIMPLEX" MECHANICAL TELEPHONE.

This instrument, being entirely mechanical, is of very simple construction. No batteries are required, and there is nothing in the instrument which can get out of order or require attention. It is not affected by electrical "induction" or "interruption," and where the distance is not too great, it is more efficient than electric telephones. A single instrument acts as transmitter and receiver at each end, the two being connected by a tense steel wire; and there being nothing to hold, the hands are free to write down, if necessary, any message. To call attention, tapping on the diaphragm of the telephone is often found sufficient. Magneto-electric call-bells are, however, sometimes used. No batteries are required for these, nor is a separate wire necessary. It will be found invaluable to practitioners having partners, assistants, surgeries, or stables at a distance, and for connecting distant parts of hospital, etc. The cost is very small, that of the instruments being 30/- a pair only. Estimates and other particulars may be had by applying to the inventor and patentee, Mr. T. Harding Churton, 35, Park-square, Leeds.

91.—APPARATUS FOR VOLUMETRIC ANALYSIS.

THE accompanying drawing explains Messrs. Poths and Co's. (Leadenhall-street, London,) apparatus for volumetric analysis. It is made in strict conformity with the one mentioned at page 488 of the

'British Pharmacopœia,' for British weights and measures, though it can be had estimated in grammes if desired. The makers have wisely added a long glass rod, which will be found highly serviceable. In these times when great efforts are made to bring the standard of scientific education of chemists and druggists to a higher level, and when the examinations are made more difficult, a great many assistants might avail themselves of this convenient way of possessing themselves of such a set of apparatus, as offered by them, and their offer will perhaps cause many chemists and druggists already established, but not having any as yet, to make up their minds to get one. We direct attention to two points: 1. The convenience of obtaining these apparatus ready packed from stock without having to specify the items separate. 2. The very moderate price which include packing and carriage to any part of the United Kingdom—viz., 10/- each.

Medical Miscellanea.

THE subject of our next illustration will be George J. Allman, M.D., LL.D., F.R.C.S.I., F.R.S.

The Pasteur Institute now in process of construction at Vaugirard will cost 1,500,000 francs.

Sir J. Crichton Browne has been elected President of the Neurological Society of London.

The personal estate of Sir George Burrows has been valued at £104,628.

The *Scientific Enquirer* is still published under the able editorship of Mr. Allen.

Dr. Wesley Carpenter, New York, one of the ablest literateurs in the United States, died suddenly on January 7th.

The Berlin police have warned the public as to the value of Warner's "Safe Cure," sold for four marks a bottle. The remedy is said to consist of American winter green.

We direct the attention of our readers to the admirable discussion which took place at the Liverpool Medical Institute on "Excision of the Knee."

The late Dr. Hamilton, Cookstown, Ireland, was an old Poor-law officer; he was for forty-six years Poor-law officer of Cookstown Workhouse.

A National Pension Fund for Nurses is now being incorporated. £20,000 has been deposited with the Court of Chancery for a working fund. This sum was given by Lord Rothschild, Mr. H. H. Gibbs, Mr. P. Hanibro, and Mr. J. S. Morgan.

Mr. George St. George, surgeon to the Co. Antrim Infirmary, has presented a most satisfactory report to the governors, and he is to be congratulated on the successful surgical result of his cases, major and minor.

Our confrere, Dr. Alfred J. H. Crespi, of Wimbourne, is engaged in other literary work in addition to that which he is doing for our columns. A lengthy article from his pen on "The Relation of the Physician to Dying Patients" will shortly appear in the *Nineteenth Century*, as well as other papers in the *Cornhill* and *Tinsley's*; the last has been revised with some energy, and is well printed and readable.

The *New York Medical Record* says: "A dispute has lately arisen in Paris between M. Zola and M. Sarcy over the question whether asses can vomit. Asses cannot under ordinary circumstances vomit. But they are not given a fair chance. Let the poor animals have read to them some of M. Zola's wash-tub realism, or say one of his chapters on obstetrics, small-pox or delirium tremens. Then observe the emesis.

We are pleased to record a graceful act on the part of the Manchester, Sheffield, and Lincolnshire Railway Company. After the Hexthorpe accident a large number of patients were taken to the Doncaster Infirmary. The Company have voted £50 to Mr. Penny, the house surgeon, in recognition of the additional labours imposed upon him, and with the best thanks of the Board, besides giving a donation of £250 to the Infirmary.

Some members of our profession have lately died at an advanced age—viz., Mr. Monk, surgeon, Preston, aged ninety; Dr. Sealey, Bridge End, seventy-six; Dr. Bailey, West Chester, Pens., eighty-seven; Dr. Walker, Peterborough, ninety-one; Mr. Silvester, ninety-nine; Dr. Ogsten, Aberdeen, eighty-four; Dr. Neklewitsch, Poland, 109; Dr. Prudy, New York, seventy-six; Dr. Hatfield, Philadelphia, eighty-three.

Pasteur's method has been simplified.—We learn from the *Medical News* that Dr. Högyes, of Buda-Pesth, has published in the *Orvosi Hetilap* an account of some researches he has made on the protection of dogs from rabies by a somewhat simpler method than that employed by Pasteur. He, too, makes use of the spinal cord of an infected rabbit, but instead of drying it to a gradually increasing extent to obtain various degrees of activity, he merely rubs it up with water containing chloride of sodium so as to make solutions varying in strength from 1-10th to 1-500th. The dog to be protected is injected successively with these, beginning with the weakest. The results appeared to be quite satisfactory, and a complete immunity from rabies to be secured by six of these injections.

TO ADVERTISERS.

THE attention of the proprietors of this journal has been drawn to a surcharge by the postal authorities upon the printed circulars sent out by the advertising department. The proprietors would feel greatly obliged if any persons who have been charged excess postage would kindly communicate with Mr. Bella, at the London office, 58, Charing Cross-road, who will immediately refund all expenses. As will have been seen by the recipients of such circulars, there is nothing which infringes the regulations of the postal authorities, and the prejudice caused by the ignorant action of local postmasters through excess of zeal is much to be deplored. The attention of the authorities has been duly drawn to the matter, and after the customary delay of three or four months, they will probably issue the stereotyped apology in use under similar circumstances.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "The Provincial Medical Journal," Horton House, Halifax.

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester; or to the London Representative, Mr. E. BELLA, 58, Charing Cross Road, W.C., to whom all communications respecting Advertisements should be addressed.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

THE PRACTICAL VALUE OF THE M.D. DEGREE.

To the Editor of "The Provincial Medical Journal."

SIR,—The question of the granting of degrees in medicine and surgery, which has been so long, like a slumbering volcano, making its presence known by murmurings and occasional tiny explosions, has suddenly taken an acute form, and a crisis (which may be taken to correspond with the eruption) seems imminent. The initials "M.D." after a man's name seem to very many, so far as can be judged from the controversy which has long been carried on, to be the *summum bonum* of medical professional requirements, and to be possessed of the right to append them, as imparting a magical influence and power. The appendix "M.D." seems to some to bear to all other medical and surgical qualifications the same relative importance as the sun bears to the remainder of the planetary system: it dazzles, and seems to them to imply that all the others should pale before it. It seems the very acme of professional bliss, and its possession the remedy for all "those ills we have" as a body. Whether the views of those who are thus clamouring and striving will be found to tally with those of men who have already entered the cabalistic "M.D." portal is more than questionable. The wailing cry of "*Medical Degrees for London Students*" has, as was inevitable, been taken up by all the numerous licensing bodies in the United Kingdom; while on the other hand, the universities have been, from their peculiar composition, the only corporations hitherto entitled to grant a doctor's degree of any kind, are roused to opposition, in order to preserve what they term their liberties, but as we prefer to call them, their privileges. The move made jointly by the Royal Colleges of Physicians and of Surgeons, of London, is now followed by a similar action on the part of the Scottish licensing bodies—viz., the Royal Colleges of Physicians and of Surgeons, of Edinburgh, and the Faculty of Physicians and Surgeons of Glasgow. Other independent bodies, from all parts of the kingdom, unconnected with either of the foregoing, are now certain to enter the arena and join issue. This will undoubtedly be followed by a combination of the remaining universities, when the battle will become general all along the line. Whether the issue at stake is worthy of the importance thus attached to it is, from the numerous points of view from which it may

be regarded, a mere matter of opinion. But from one of these aspects, there is only one answer possible, which will be best contained in the reply to this question: What is the *practical* value of the M.D. degree to members of the medical profession? By holding it, do they become in any way more learned? Do they become in any way better practitioners? Are they rendered more competent to deal with disease and the public health? Is their general position in any way improved by it? Are they in any way rendered superior men to those who may either not choose to obtain the degree, or through any other circumstances be prevented from proceeding to obtain it? Are professional fees either raised or affected? Are there any special privileges acquired?

Let us suppose that every duly-qualified medical practitioner in the British dominions held the degree of M.D.—what would be the condition of affairs? Each man's relative position would remain unaltered. Professional ability is not a matter of degree, or of this or that qualification, but one of purely personal character. Medical practitioners would not in any way rise in the estimation of the public. What would be considered is practical ability, the power to perform the physician's or the surgeon's work well and genuinely. Look at the state of things to-day in any of our towns where medical men are numerous—the best practices and widest *clienteles* are found most frequently in the cases of men who hold what some are pleased to call minor qualifications, while others who hold what are similarly termed high qualifications may have little or nothing in the way of practice. It is already found that neither Doctorates or Fellowships avail anything if certain personal qualifications are absent. The latter are not to be acquired by passing any number of examinations, or obtaining any series of diplomas, any more than it is possible to convert any ordinary individual into a gentleman by giving him a complete university curriculum. Assuming, then, that every registered practitioner were an M.D., the struggle for superiority would continue, and anything like equality (which appears to be the great desire underlying all this fermentation) would be as far off realisation as ever: the conditions of every-day life would remain unchanged; competition would be just as keen; and personal, natural differences would tell in the end just as powerfully.

"Necessity will make us all forsworn

Three thousand times within this three years space;

For every man with his affects is born,

Not by might master'd, but by special grace."

(*Love's Labour Lost*, Act I., Scene I.)

The whole thing would likely degenerate into an extension of the present fashion of squabbling about the superiority of the various schools. The M.D. London would declare his degree better than the M.D. Cantab.; the Oxford graduate would insist on being considered better than either; while the M.D. of Manchester or Birmingham would claim to be better qualified than all put together. While this is going on, it may probably be found that some pushing individual, located in some obscure street, with a five-dollar bogus diploma, is doing a larger practice, and earning perhaps twice the income of any two of such highly-qualified gentlemen.

The actual value of any qualification will never be positively ascertainable until all are made to pass through the same ordeal—through a State examination uniformly imposed; then, and then only, will a man's academical powers be allowed to show themselves, and the amount of actual medical or surgical knowledge he has shown the ability to acquire be evinced. That this should ever be the case is, so far as we can at present judge, most improbable. With regard to the point we have raised, the actual practical worth of any medical degree to the practitioner is but small, and it seems sad to see licensing corporations of such ancient standing and honourable records striving to subvert their own time-honoured and revered membership and licenses in order to adopt a bare formal proceeding, in order to bestow upon their licentiates what, if they succeed in extinguishing their own distinguishing titles, will go far to efface themselves as corporations from the number of licensing bodies, for the sake of bestowing what to the recipients will prove little better than a mythical title.—Yours truly,

A BONA FIDE M.D.

ALCOHOLISM AND STRYCHNIA.

To the Editor of "The Provincial Medical Journal."

SIR,—As to the value of the treatment of chronic alcoholism by strychnia, there can, I think, be no doubt; but to affirm as some authorities do, that the one is antidotal to the other, is to put a wrong construction upon the effects observed. In all chronic cases of this very common complaint the blood is reduced in fibrin and hæmoglobin, as is shown by the cadaverous and bloated appearance of every drunkard; and this is to be explained by the deleterious and well-known action of alcohol upon the liver. In addition to this, the effect of the drug is to stimulate and dilate the peripheral capillary circulation. By continual

stimulation of the circulation, and consequent continual dilatation of the peripheral capillaries, debility of their walls, and delayed peripheral circulation are induced, with consequent drain of fluids from the central capillary system. Hence the continual thirst of a confirmed drunkard. The more he drinks the more intense becomes his desire to drink yet again; not so much, or altogether, because he likes the taste, as because his throat is dry and parched. Herein lies the value of strychnia. By its powerful tonic action on the peripheral and central capillary walls, it lessens the "circulatory cavern" the drunkard in vain tries to fill, and thus brings about a healthy because a moderate desire for liquids.—I am, Sir, your obedient servant,

Clayton-le-Moors,
February 6th, 1888.

C. K. ILLINGWORTH, M.D., M.R.C.S.

TARDY CONVALESCENCE IN THE PUERPERAL STATE.

To the Editor of "The Provincial Medical Journal."

SIR,—Like your correspondant "J.M.G.," I have had several cases of the above, and should be glad of any suggestions for their better management. One case now under my care is that of a healthy patient who was delivered of her third child on November 24th, 1887. The labour was perfectly natural in every way, and for the first week the condition of the patient was satisfactory. She then began to perspire rather freely and to complain of feeling weak and exhausted, although she was able to partake plentifully of nourishment. The lochia continued for a fortnight after delivery, when she got up and began to move about. The perspiration gradually ceased, and during the third week there was a slight muco-purulent discharge, which was soon controlled by the use of injections. She never complained of much pain; the temperature was never above 100° F. I could discover nothing physically wrong either by external examination or *per vaginam*; and although it is more than two months since she was delivered, she is only now beginning to "feel herself," and is still far from being well. Although this has been the most tedious case I have had still, it is not the only one of the kind, and I should be very glad to know what treatment one can adopt in such cases, beyond rest, good nourishment, quinine, iron and general tonics.—Yours truly,

Bolton, February 6th, 1888.

J. JOHNSTON, M.D., EDIN.

WHEN SHOULD THE UMBILICAL CORD BE TIED?

To the Editor of "The Provincial Medical Journal."

SIR,—Undoubtedly an erroneous theory concerning the tying of the umbilical cord at birth is gaining some attention. It is claimed that late tying is desirable. Nothing could be more undesirable. The best method is to tie as soon after the birth of the infant as possible, not waiting for the expulsion of the placenta or after-birth. As soon, indeed, as the infant breaths the cord should be tied. The fact that the infant is more sleepy, and does not begin to drink so soon when the cord is tied late, is in itself proof positive that the blood left in the placenta after expulsion is *not desirable* for the nutrition of the infant. If, as Dr. Eagle recommended, the cord be tied late, good arterial blood is lost thereby for poor venous blood. The supply of arterial blood lost by late tying is only in part returned by venous blood. The importance of early tying is to start the little infant with the best supply of blood possible, so that the purest of blood-making may go on normally in the future. This is a very important fact to consider. Late tying, therefore, has other objections than the immediate injury of the infant: its ill effects are far reaching. Undoubtedly, considerable future mental and physical suffering can be induced by late tying. Infant life is so quickly and seriously influenced by what might seem to the careless observer merest trifles. The cord should be tied at least two and a half or three inches from the body, with a firm cotton cord in a surgeon's knot, and another ligature should be taken an inch from this to prevent the bleeding of the after-birth veins. The cord should be cut with scissors between the two ligatures.

No patent clamps, tape, or rubber bands should be used. Nothing can be better than the clean cotton cord, uncoloured. The cord may be "medicated" by soaking it in "boracic" before it is used. Carelessness in tying or dressing the cord has often resulted in serious danger to life, and sometimes has been of lasting injury.

The cord should be dressed with T. Metcalf's "boracic ointment," which is especially valuable for use in such cases, and will be found very superior to all other preparations, in that it does not become sour, but really possesses strong disinfectant and restorative powers. It is clean and wholesome, and never disappoints. This ointment should be spread on fine linen, and applied with great gentleness.—I am, Sir, yours truly,

Newport, R.I.,
February 19th.

W. THORNTON PARKER, M.D.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

THE Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VII.]

APRIL 2, 1888.

[No. 76.]

Our Portrait Gallery.

GEORGE JAMES ALLMAN, M.D., LL.D., F.R.C.S.I.,
F.R.S., F.R.S.E., CORR. M.Z.S.L.

THE subject of our illustration, according to *Men of the Time*, was born in Cork in 1812. He was educated at the Belfast Academic Institution. For a short time his mind was directed to politics, and he decided on studying for the Irish bar. His love of biological science, however, proved too strong, and before he had completed the required number of terms he gave up the study of law for that of medicine.

He graduated in Arts and Medicine in the University of Dublin in 1844. In the same year he was appointed to the Regius Professorship of Botany in that university, when he relinquished all further thought of medical practice. In 1854 he was elected a Fellow of the Royal Society, and in 1855 he resigned his professorship in the University of Dublin on his appointment to the Regius Professorship of Natural History in the University of Edinburgh, which he held till 1870, when the state of his health compelled him to resign it. Shortly after this the hon. degree of LL.D. was conferred upon him by the University of Edinburgh. His chief scientific labours have been among the lower members of the animal kingdom, to the investigation of whose structure and development he has specially devoted himself. For his researches in this department of biology the Royal Society of Edinburgh awarded to him in 1872 the Brisbane prize. In the following year a royal medal was awarded to him by the Royal Society of London, and, in 1878, he received the Cunningham Gold Medal from the Royal Irish Academy. He was one of the Commissioners appointed by the Government in 1876 to inquire into the state of the Queen's Colleges in Ireland. Soon after his election to the Edinburgh chair he was nominated one of the Commissioners of Scottish Fisheries—an honorary

post—which he continued to hold until the abolition of the Board in 1881. On the occasion of the General Election in 1874, the Committee for securing the return of a Liberal member for the borough of Bandon selected him for nomination, at the same time offering to relieve him from the necessity of pledging himself on any of the special questions which then formed a prominent element in Irish politics, but he declined the proffered honour. The same year, on the resignation of Mr. Bentham, he was elected to the presidency of the Linnean Society, which he held until 1883, when he resigned in favour of Sir John Lubbock.

In 1878 he was elected President of the British Association for the Advancement of Science, at the meeting held in Sheffield in 1879. On the completion of the exploring voyage of the *Challenger*, the large collection of Hydroida made during the great expedition was assigned to him for determination and description—a service which he had already performed for the Hydroida collected during the exploration of the Gulf Stream, under the direction of the United States Government. Results of his original investigations are contained in memoirs published in the *Philosophical Transactions*, *Transactions* of the Royal Society of Edinburgh, the *Transactions* of the Royal Irish Academy, and the *Transactions* of the Linnean and Zoological Societies of London, as well as in Reports presented to the British Association for the Advancement of Science; to the Mus. Comp. Zool., Harvard University, and to the Commission of the *Challenger* Exploration; also in communications to the *Annals of Natural History*, the *Quarterly Journal of Microscopic Science*, and other scientific journals. His more elaborate works are "A Monograph of the Fresh-water Polyzoa," fol., 1856; and "A Monograph of the Gymnoblasic Hydroids," fol., 1871-72, both published by the Ray Society, and largely illustrated with coloured plates. He is a Member of the Royal Dublin Society, and honorary member of various British and foreign societies.

A NEW LITHOTOMY OPERATION.

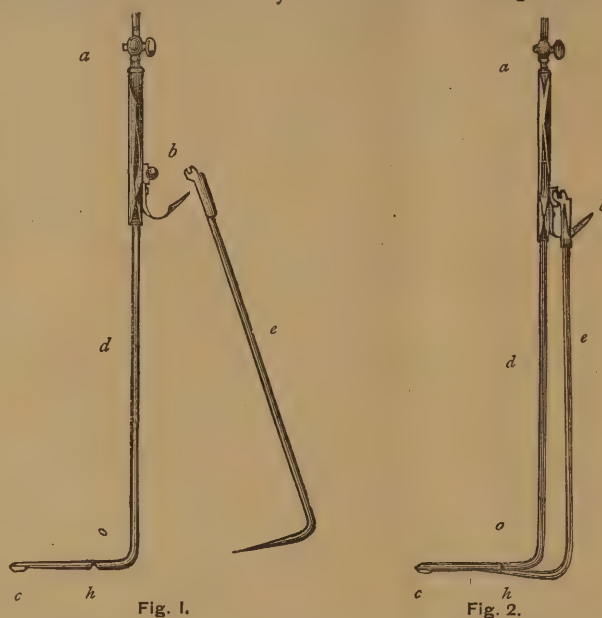

BY HUGH OWEN THOMAS (LIVERPOOL).

MANY modifications of the old lateral operation of lithotomy have been introduced into surgery during the last century, mostly devised to minimize its dangers, yet in some degree to lessen the amount of manual dexterity—required for the successful performance of the operation. I have operated up to this date upon thirty cases; not an extensive experience, true, but this number affords a fair opportunity of becoming familiar with the operation. The first case in which I operated, the ordinary curved staff with lateral groove was used; the incision and penetration were performed with an ordinary scalpel; the case was a success; and on cogitation it appeared to me to be an unsatisfactory manner of incising the bladder for the removal of stone, too much being left to the surgeon's skill. On reviewing the various methods, Civiale's medio-bilateral operation presented an important advantage, as it afforded a larger incision on entering the bladder, and consequently caused less injury in withdrawing the stone. This operation I performed twice, using his curved median staff and double-bladed bistoury. These two cases were also successful, but there was secondary hæmorrhage in both instances; this mode of operation appears to be safer and simpler on paper than in practice. My next change occurred when Mr. Hutchinson published his medio-bilateral operation with rectangular staff and median groove, flat bilateral cutting gorget, with probe point. One operation I performed by Hutchinson's method; this was a success; but as a whole the mode of operation did not satisfy me; nevertheless, Mr. Hutchinson's hollow staff, with median groove, excited my admiration, and I decided, that if I operated again, to employ this excellent instrument in combination with Civiale's double-bladed bistoury. This decision I was able to test, and was so pleased that I thought I had now a plan of operation which would come up to my ideal. Before long I discovered in Braithwaite's "Retrospect" a description of Dr. Corbett's double rectangular staff with lateral grooves. This, I at once saw, could be adapted to the median operation, and I planned a method and means of operation which may be said to be copied from—The old operation, a scalpel; from Dr. Buchanan's rectangular staff (how I was ever so obtuse as to use a curved staff I cannot explain); Hutchinson's median groove; Civiale's bilateral incision; Corbett's double staff; these I combined, with a small contribution by "Thomas," so that I believe the method I am about to describe can be performed with but little risk to the patient, requiring less manual dexterity on the part of the surgeon than any other method. From the moment of incising the skin of the perineum to opening the bladder, there is no interruption or change of instruments, the only merit of the old lateral operation.

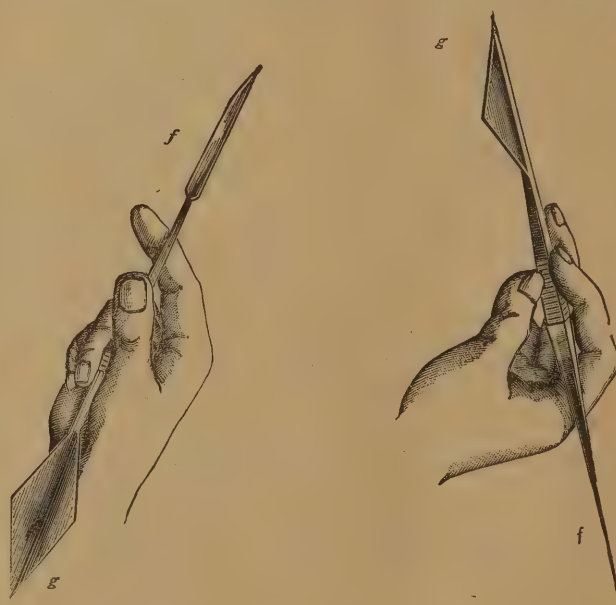

In my earlier experience of the medio-bilateral operation, I noticed that—though my cases always did well, losing only two out of thirty, one a child nine months, and an adult of sixty-four—secondary hæmorrhage occurred out of proportion to the number of cases operated upon; but, as—in my opinion—I perfected the means for, and the manner of operating, I no longer noticed any cases of

secondary hæmorrhage; indeed, the majority of those treated in later years were almost bloodless.

Fig. 1 is an illustration of the urethral and extra urethral staffs disconnected from each other by means of a hinge *b*. The urethral staff is hollow up to the right angle, from whence the median groove commences and terminates at the wooden cylinder sunk into the groove at

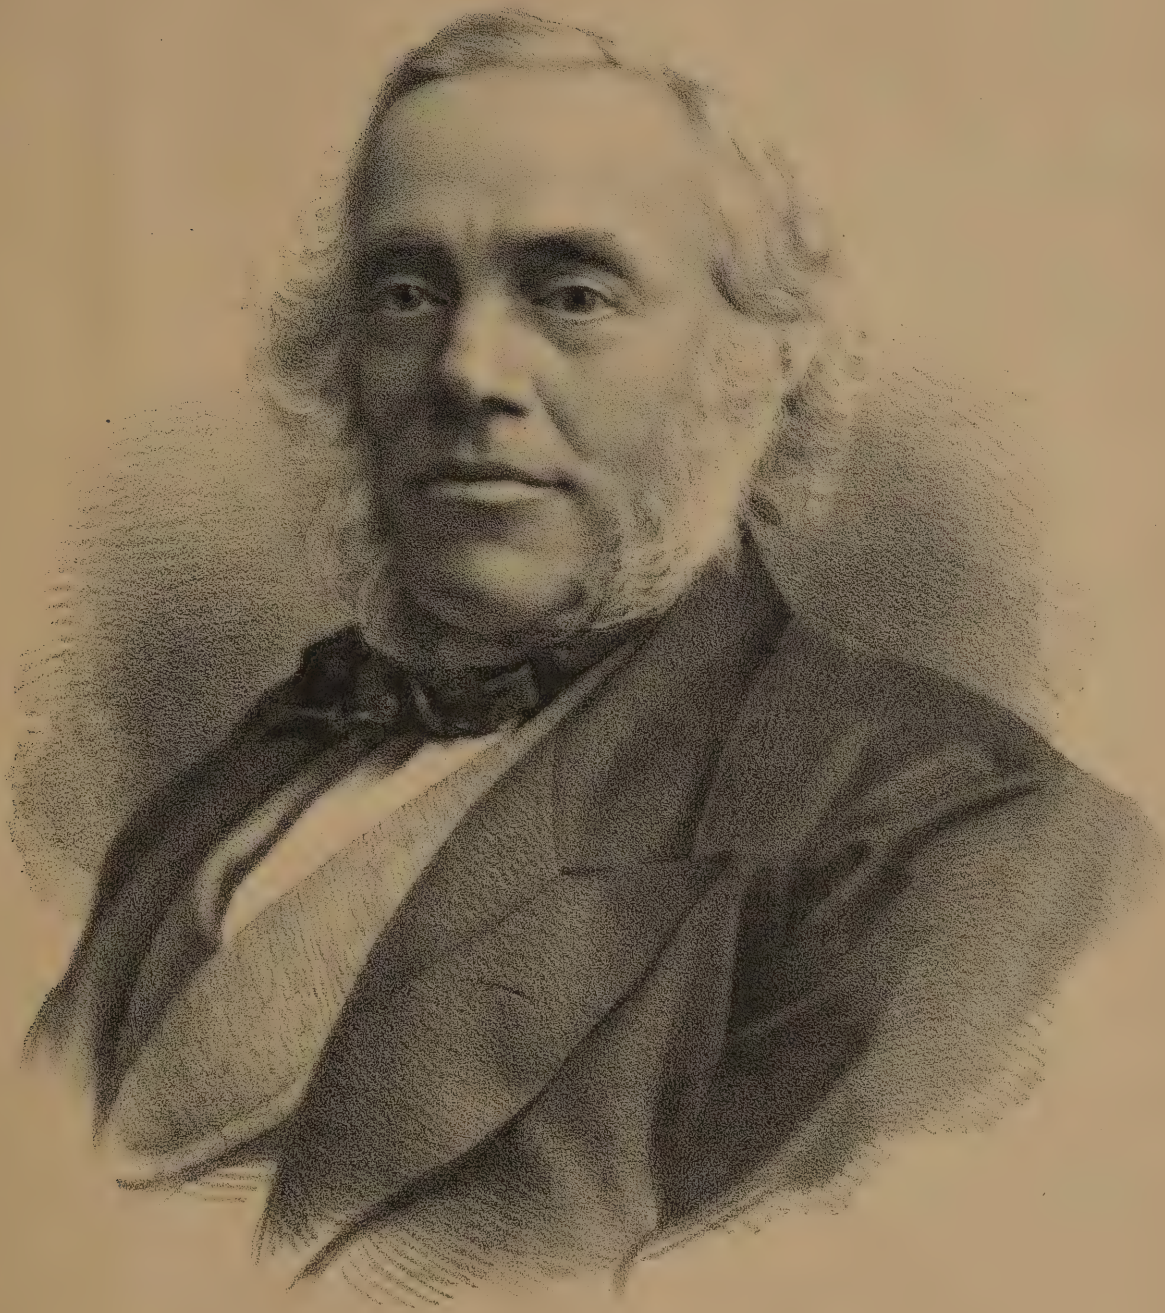

c. At *a* is a stop cock for retention of fluid injected into the bladder before operating. Situated at about an inch from the angle is a notch partly secting the median groove—fig. 1 *h*. The joint at *b* unlocks when the extra-urethral

staff is at right angles to the urethral one, but cannot escape; as soon as it descends parallel with the other, it is then locked by an ordinary spring catch.

Fig. 2 shows the instrument as in operation. The

Very truly yours
Geo. S. Allen

second staff is also grooved and pointed, so as, when in use, to enter and sink into the groove of the first staff at the notch (*h*) only. It is very necessary that the instrument maker when constructing the second staff, should make its angle, so that when it is in position, it is a little lower than that of the first one; otherwise, the second staff in describing an arc to enter the perineum will enter high and lock low, which may lead the surgeon to make his incisions rather high, whereas by attention to making the second staff a little longer than the first, it enters the perineum low, and gradually rises to the notch, thus almost certainly protecting the bulb and its artery.

Fig. 3 shows the instrument grasped by the hand, as in the manner of operating when about to incise the perineum; this instrument is a combination of a scalpel blade at one end *f*, and a cutting triangular gorget *g* at the other end.

Fig. 4 shows the same instrument reversed, and held as when in the act of sliding along the double grooves of the staffs to incise the membranous portion of the urethra and prostate. The operation comes under the class of "medio-bilateral with rectangular staff," and is performed by me in this manner. The patient being placed in the usual lithotomy position, the urethral staff is passed and the viscus is distended with two or three ounces of water, and retained by shutting the stop-cock; and the handle of the single staff is handed to an assistant, who is directed to hold it at right angles to the trunk. The next step is that the index-finger of the left hand is passed into the rectum, and on its finding the membranous portion of the urethra, the surgeon so locates the urethral staff in charge of the assistant that he (the operator) can feel the notch, fig. 1, *h*, in the membranous portion of the urethra, close to the prostate, still retaining the finger in the rectum. With the scalpel end of the combination instrument, as seen in fig. 3, a perpendicular incision is made in the median line of the perineum, commencing about two inches above the anus, and terminating about half an inch from its edge. This incision is crossed by another at right angles to it at its lowest end, about one and a half inches in length, so that the incisions present the lines of an inverted T—thus, \perp ; then guided by the finger in the rectum with a few strokes of the scalpel, the skin and other superficial structures are divided, advancing by careful dissection as close as practicable to the rectum, without wounding it in the direction of the membranous urethra, until progress is made to a point supposed to lie underneath the bulb when the second staff (which was in position ready for action) is brought down, and its sharp point made to enter the wound and come to a stop on piercing the urethra at the notch *h*, fig. 2, when, perhaps, a little fluid may escape. The surgeon instantly reverses his cutting instrument as shown in fig. 4, places the ridge of the triangular gorget *g* in the median groove of the second staff, pushing it forward until its further progress is arrested by its point coming in contact with the wooden cylinder *c*, on the extreme end of the urethral staff; the liquid contents of the bladder run out, and the surgeon withdraws his finger from the rectum and inserts it through the bilateral incision made in the prostate, and over the finger the gorget is now withdrawn, then the stone felt for, the staffs are removed and the stone extracted.

The operation is really easier to perform than this description would lead the surgeon to suppose, provided the two staffs are properly constructed in relation to each other. They should be both rectangular, or, if any

deviation is made, the angle should be slightly less than a right angle; and the angle of the second staff should be slightly lower than that of the first when locked home. This causes the gorget to enter low in the perineum, and rise to its work rather than advance horizontally to incise the membranous urethra and prostate. I am aware that other surgeons have introduced to our notice double lithotomy staffs, for instance, at page 451, in the third edition of Mr. Harrison's "Lectures on Surgical Disorders of the Urinary Organs," we have an illustration of a double lithotomy staff, and blunt-pointed, but cutting-edged gorget, a modification of a similar form introduced to the notice of the profession thirty years ago. The original one, its predecessor, having a cutting instrument attached to the second staff by a hinge, whereas, the latter, devised by Dr. Smith, of Baltimore, uses the gorget disconnected from the staffs. On carefully examining the illustration of Dr. Smith's instrument I noticed that the angle of the urethral staff was curved, and much more obtuse than a right angle. This is, in my opinion, provided that the staff were held in the usual manner, or the manner in which I have instructed, a very dangerous instrument to employ, but I find from the position of the hand in the illustration that it is intended to be held by the operator's left hand, while with the right hand he uses the gorget. This manner of performing the operation enables the operator to practically reduce the obtuse angle of his instrument to a right angle, or even less. This leaves one item, at least, to the operator's judgment, which Corbett's instrument, or its modification by myself, does not.

Small contributions are sometimes thankfully received, and here are submitted to the reader what little I have to contribute concerning the after treatment of lithotomy. It appears to me that to this part of the operation surgeons of large experience have given us but little information. In early years, during my search for information by which to interpret unwelcome symptoms, I obtained very little assistance, and it is remarkable that surgeons who have performed their scores of lithotomies have not published a series of typical cases illustrative of the after treatment and its complications. One case would do, for instance, in which the patient operated upon recovered in a few days. Of such cases we have plenty of reports already; but more of those cases would be welcomed in which the patient, whether he recovered or not, had grave symptoms. These are the cases for which a beginner searches in vain when about to try his skill as a lithotomist. The first thing to which the surgeon gives his attention, after extracting the stone, and washing out the bladder, is the question of placing a drainage-tube in the wound. It is my invariable practice to put as large a drainage-tube in the wound as it will admit. For a long time I employed glass tubes. Of late years I prefer rubber ones; and no tube which I have ever seen devised appears to me to answer so well as a strong rubber one, having the same diameter of opening at both ends. The tube is retained in position by a thread passed through its diameter, and attached to thread loops, which have already been prepared by suturing the skin over the ischium. The patient now has a large bib placed under him, into which has been laid a good supply of medicated sawdust, to which has been added a small percentage of precipitated chalk; this is changed two or three times a day. Now an opiate is given to the patient, and as the bowels have been cleaned by a purgative and an enema before the operations, they need not be disturbed until spontaneous action occurs,

which can be safely allowed, even if we have to wait for one or two weeks, provided the patient's diet is properly selected to meet the requirements of our intentions. It has been my practice to leave the perineal tube to drain the bladder until all the constitutional signs of operative procedure, and traces of any lesion caused by the pressure of the stone in the viscus, had passed away. No matter how well the patient may progress, I always retain it three days at least, and when the tube is finally withdrawn, the bladder is drained—per urethram—with that convenient device, the elastic rubber catheter, changing and cleaning the catheter night and morning; occasionally also washing out the viscus through the catheter with a weak solution of chloride of zinc.

Some patients at first rather object to urethral drainage, but I found when discontinued they invariably request its re-adoption, as it materially diminishes the urinary irritation felt at the perineal wound. As to the mishaps of lithotomy, my two fatal cases bring to my recollection a comment by Sir W. Ferguson made in his "Lectures on the Progress of Modern Surgery," to this effect: "he had witnessed the most skilful operations terminate fatally, and very unskilfully performed ones progress exceedingly well." To my mind the last case which was fatal in my practice was the best performed of any, not half an ounce of blood was lost; the only hitch that occurred arose from my supposing the stone to be rather smaller than it turned out to be, so that my prostatic incision was too limited, and had to be enlarged to rectify my error; this kept the patient an extra five minutes under ether, so causing him to have been under the influence of the ether from the commencement of its administration until completion of operation, fully half an hour. To the prolonged action of the anæsthetic upon a well worn man of sixty-two years of age with highly atheromatous arteries, I chiefly attribute the fatal termination. During the first three days, with the exception of a dry, brown tongue, there were no grave symptoms of constitutional disturbance. On the third day he was seized with vomiting which lasted a few hours, and was followed by hypostatic congestion of both lungs, and he succumbed apparently to this lesion on the fifth day. The other fatal case was a child twelve months old. Here again there was a delay in the extraction of the stone; it could be easily felt on the introduction of the finger, but its detection by the forceps was not so easy as it lay up high behind the pubes. Its extraction delayed the operation five minutes. Again as the cause of fatality in both cases, it is very significant that the infant was subjected to no preliminary preparation, and the adult to only three days, and as I have committed this omission on five occasions, every one of which operations were followed by grave symptoms, I cannot help but think that a week or two, perhaps more, of preparation, which is my usual practice, to be a valuable item towards success. Last year a patient of seventy-two years of age was operated upon, a most uninviting subject. Six weeks were devoted to his preparation, and he did exceptionally well. Twice have I successfully at the advanced age of 72 years, and from one removed seven calculi each of three quarters of an inch diameter. He was an asthmatic subject, and had angular deformity of left hip-joint. He returned to me twelve months afterwards for examination and on sounding the viscus, there was evidence of his having made up for his loss, there had formed another nest of calculi. On this occasion he declined to be recut, not an unwise decision as he appeared, independently of his

years, a well worn man, though not a confirmed invalid. Once I recut a boy of three and a half years, and extracted a stone, though six months previously another had been removed while he was an inmate of a public hospital. On another occasion after incising the viscus there was extracted the wooden holder of a writing pen.

I have been much impressed during my experience of lithotomy by the better progress of cases which had been prepared, as compared with those which had only a short period of introduction to the operation. To the most unwelcome of the two cases of seventy-two years, I gave six weeks' preparation, and succeeded, though several surgeons formulated the opinion that lithotomy was highly risky. For most cases, however, two weeks is sufficient, during which time the patient should be kept reclining in bed, in a warm room, diet selected, light and nourishing; and just a day or two before the operation the diet should be selected, in view of the purgative to be given a day before the operation, so as to make sure that the bowels are free from excreta, and that the aperient acts without discomfort, and probably brings down most of the bowels' contents to the rectum, to be washed out a few hours before the operation is commenced.

As regards the prevention of secondary hæmorrhage, it is my practice to use a rather capacious tube, with "parallel bore," and as large as the wound will admit, retained three or four days; and should the urine drained appear much coloured, or a blood-clot deposit in the bladder, the tube ought to be retained even longer. When the urine comes away colourless, a slightly smaller tube can be daily substituted, gradually reducing until the surgeon's anxiety has passed away. The urine may flow coloured for a few days from the presence of more or less clot in the bladder, the result, perhaps, of mere oozing into the viscus during the few first hours after operating. It is often said that this is of no consequence. A small clot is, probably, of no moment, but except it be small, it may give the patient nearly as much discomfort as a calculi; but should there be allowed for a few hours a large clot, the patient generally shows the signs of irritative fever, and here large perineal tubes with parallel bores become extra serviceable, as small clots can be washed out through them, and large clots can be broken up by the introduction of a suitable long probe, and afterwards washed away; or as I have done, a urethral forceps can be introduced, clot broken and withdrawn, and then thoroughly, antiseptically, washing out the viscus. It is my practice, as I before mentioned, as soon as the perineal tube has answered its purpose, to introduce an india-rubber catheter per urethram, and divert the urine from the wound. The operation is sometimes difficult of performance if the surgeon has not carefully selected his rubber catheters. Some of them are sold with solid ends up to the eye. These, when wire styleted, and introduced, and they begin to pass under the pubes, the stylet comes out through the eye, giving pain to the patient and alarm, perhaps, to the surgeon, who notices a slight bleeding from the perineal wound. To avoid this difficulty, let the surgeon purchase only those rubber catheters which, on examination, he finds are hollowed well past the eye, and feel soft at the end, showing the end is coned hollow, and when about to use the catheter, to draw it over the stylet, so that its eye is on the convex side of the stylet, and also make sure that it does not rotate from that aspect during introduction.

My experience of secondary hæmorrhage consists of only two cases of lithotomy, and one of perineal section.

The mishap in the two lithotomy cases, I attribute to entering the perineum not so low down as I do now; a fault of my earlier operations. The first case was operated upon November 20th, 1868; the second, November 7th, 1873. The first case bled the fifth day after the operation, when the drainage-tube—which was small—not acting, the patient became feverish and delirious. He was placed to sit in warm water, which relieved the constitutional symptoms, but was followed in a few hours by an alarming hæmorrhage. Now there was done—what should have been done before—an exploration of the wound with an oiled finger; tube introduced, and wound plugged around it. This did not answer the purpose, so it was removed, and the wound dilated with a female urethra dilator, and the large clot which I found in the bladder was removed with the urethral forceps. The dilator was retained inside two days, when it was removed, and in its place was introduced a small bivalve rectum speculum, which was removed in three days, and the patient after this did very well. The patient's age was about twenty-five years. The stone was a round mulberry two inches in diameter.

My second case in which hæmorrhage occurred, the tube was removed November 11th, four days after the operation. November 13th, slight bleeding occurred, and the tube re-introduced, and retained three days, which arrested the hæmorrhage. Again, one day after removal of tube, there was free bleeding which was controlled by pressure of the finger on the left side of the wound. This was withdrawn after three hours, and a large tube introduced, and the patient remained free from hæmorrhage until November 27. Then a large tube, with three-quarter's of an inch bore, containing ice was introduced; nevertheless, November 30th, bleeding occurred again, and the bladder became full of clot. This was removed by suction. December 6th, bled again. Now a glass tube was carefully fixed obliquely in the wound, so as to press on the left side of the wound. This was retained until December 22nd, when a rubber catheter was passed into the bladder to drain, per urethram, and the case rapidly recovered after this date.

The third case of hæmorrhage occurred after perineal section to relieve stricture. Blood persistently oozed from the wound for three days, and the patient became so drained that he appeared much blanched, and I decided to put a tube in the wound, and firmly stitch the wound with deep sutures, and thus arrest what was only a general oozing, using a large curved strong needle for the purpose; but, to my astonishment, the blood draining from the suture holes appeared as great as that from the wound, so the sutures and tube were removed, the pelvis well elevated and the bladder well syringed out with strong chloride of zinc solution. This case did well.

The mishap of after incising the bladder, failing to find the stone, has happened perhaps oftener than we suppose, as it is a very pardonable sin to omit reporting such cases. Modern writers upon lithotomy very seldom catalogue this amongst the complications of the operation, or refer to it at all. Lithotomists of the last and early parts of this century frequently referred to this mishap, and the mode of correction. In a famous medico-legal libel case the defendant was supposed to have "scored," when in cross-examining an eminent witness for the plaintiff, a celebrated lithotomist, it was shown that he was unacquainted with the practice of his predecessors under such a difficulty; ignorant of the operation (*à deux temps*). The perusal of the cross-examination in this case first introduced me to the procedure, which

is evidently of Gallic origin. Some time after, whilst searching some of the old medical periodicals, I found some remarks concerning lithotomy by the late Mr. Lizzars, and he gave an illustration, an episode from his own experience. Being called far away from home to remove a calculus, he performed the operation, assisted by the local practitioners; but though he had satisfied himself as to the existence of stone before the operation, on incising the bladder he could not find it. Taking the practitioners aside, he assured them, that from the experience of his predecessors, if they explored the bladder next day, they would find the stone at the incision. After giving them this information, he left for home. His advice was followed; the stone was found, and successfully extracted. From this we may conclude that if a stone cannot be found or be gripped, and afterwards lost, it would be proper practice to extract twenty-four hours after the operation, rather than prolong the initial operation.

The instruments, as shown in the illustrations, were made and excellently finished for me by Messrs. Khroné and Co., London. The angular gorgets (four sizes) being made to suit the probable extent of incision, and the staff (three sizes) suitable for the varying ages.

THE TREATMENT OF CHRONIC ULCERS OF THE LEG.¹

BY J. GORDON BLACK, M.D. LOND., HARROGATE.

SOME years ago—viz., on the 15th June, 1872—the *British Medical Journal* commenced a series of "Reports on the Treatment of Ulcers of the Leg" at the principal London and provincial hospitals. They were carefully and ably conducted, and occupied several weekly numbers. I read them with much interest, in the hope of gaining some fresh instruction upon a subject to which I had given a good deal of attention. However, in this respect the "Reports" were most disappointing reading, and I concluded their perusal with a decided conviction that the treatment of these troublesome and painful affections, at the hospitals named, was tame and inefficacious. Indeed, I could hardly resist the conclusion that, on this subject, I had learnt very little from, but had something to teach, the distinguished surgeons whose various opinions were quoted. Most of them agreed in blaming uncleanness, neglect, want of proper rest, and constitutions impaired by irregular drinking habits, as the chief causes of the ailments under consideration. One London surgeon stated that "he constantly declined attending out-patients with ulcerated legs, feeling convinced that nothing short of a revolutionary change in the habits of the London poor could justify an expectation of permanent relief. Out-patients thus refused attendance were recommended to enter the workhouse infirmary!" One cannot help pitying these poor unfortunates—their last ray of hope extinguished, and thus condemned to the "refuge for the destitute." Well might they join in the Shakespearean satire:

"He hath abandoned his physicians, madam, under whose practices he hath persecuted time with hope, and finds no other advantage in the process but only the losing of hope by time."—*All's Well that Ends Well*, Act I., Scene I.

When these reports were published, skin grafting was a somewhat recent novelty, and its efficacy in the cure of ulcers of the leg was vaunted by many of these authorities, who probably rushed eagerly to its adoption as an escape

¹ Read before the Yorkshire Branch Meeting of the British Medical Association at Wakefield, 22nd February, 1888.

from the very feebleness of other remedies. Different forms of bandaging were recommended by pretty general concurrence; but it was noticeable that no regular system seemed to be in vogue, and doubts as to the permanence of the cure were freely expressed. The main stumbling-block to its success in the hospital out-patient department appeared to be that the dressings had to be frequently renewed, owing to the accumulation of offensive discharges. One would have thought that such patients afforded an excellent opportunity for students to become proficient in neat and dextrous bandaging—a not too-frequent accomplishment—but it did not appear that such facilities were largely used or appreciated. Now, for three or four years previous to the date of these reports, I had been successfully treating all kinds of chronic ulcers of the leg by a simple method of bandaging which, in the absence of any reference thereto, I ventured to lay before the readers of the *British Medical Journal* in a paper published on 31st May, 1873. Since then I have had such satisfactory evidence of its usefulness that I desire to draw the attention of others once more to this plan of treatment. This seems to me the more necessary as I frequently see patients whose cure has been postponed by a sad lack of what may be called practical treatment.

The method I employ is based upon the system advocated by the late Thomas Baynton, a surgeon of Bristol nearly one hundred years ago. In 1797 he published his "Descriptive Account of a New Method of treating Old Ulcers of the Legs." The essential part of this treatment consisted in strapping the whole width of the affected limb with pieces of adhesive plaster spread on calico, after which the leg was carefully covered by a roller bandage from toes to knee. There is no doubt that this was a splendid advance upon previous methods of treatment, which were founded upon no definite principle. Sir Everard Home, Surgeon to St. George's Hospital, who wrote about the same time, actually recommended young practitioners to learn by rote various local applications in order that where one failed to agree with the ulcer another might be tried. Baynton, on the other hand, laid it down as a principle that efficient support should be given to the circulation of a limb, long weakened by chronic inflammation of its tissues and stagnation of its fluids. By aiding the flow of blood and lymph through their proper channels the inflammation was speedily starved out, and the profuse discharge dried up. That such a method is capable, when skilfully and perseveringly carried out, of curing even the worst cases, in a comparatively short time, I quite believe; and Baynton's memory is worthy of being revered as the pioneer. However, there are several drawbacks to the success of this plan in general practice. In the first place the plasters are apt to be stiff, and their edges prove too harsh for irritable inflamed sores. Then again, owing to the rapid accumulation and decomposition of the discharge, it is found necessary to renew the dressings at least once in every twenty-four or forty-eight hours. Now, even if the doctor be willing and painstaking enough to continue his part of the duty to its accomplishment, the patient would frequently fail in a proper attendance. There is no small amount of pain, for example, to be endured by such oft-repeated disturbance of a sensitive granulating ulcer. Every time it is exposed to the air the agony, in many cases, becomes intense until again covered up. Thus, what with the pain, the offensive discharges, the multiplied trouble and loss of time, their courage fails, and the attendances become irregular or cease altogether. Now, the

stiffness of the plasters may easily be overcome by passing them through hot water, as hot as can be borne by the hand. This effects the double purpose of softening the material upon which the plaster is spread, and rendering the latter adhesive. The strapping so treated becomes quite pliant, and may be accurately moulded to a limb without shocking even the most sensitive nerves.

The difficulty of frequent dressings is also simply removable by rendering the plasters, and the affected parts of the limb, antiseptic. So far as the plasters are concerned this object is attained by adding carbolic acid to the hot water through which they are passed. The ulcerated surface and adjacent skin may also be treated with carbolized water, but I prefer to use the sulphurous acid spray. The latter is easily employed without the operator's fingers being soiled, whilst the acid, by stimulating lymphatic absorption, tends to check the discharge of pus. It has, moreover, a very kindly healing action upon any abrasions, vesicles, or pustules which are apt to form during the course of treatment and become troublesome. Unless there is some special reason to the contrary I always use the acid full strength, both upon the ordinary skin and on the surface of the ulcer. Any smarting which may be caused is to be disregarded, for immediately the parts are covered up from the air pain ceases, or becomes insignificant. Briefly, then, my plan of treating ulcers of the leg is to use Baynton's strapping antiseptically, by which means it will be found that dressings need not be renewed oftener than once a week, even in bad cases, whilst the intervals gradually extend, as the cure proceeds, to two, three, or more weeks. Only the most serious affections require more than six to eight dressings.

The following detail may be useful in making the matter clearly understood: The patient washes the limb and ulcer with warm water, taking care to dry thoroughly with a soft towel or handkerchief. Whilst this is going on the doctor employs the time in cutting the plaster straps. These should be long enough to pass round the limb and allow the ends to overlap about four inches; width, two and a half to three inches. A sufficient number having been prepared, and some soft cotton bandage being in readiness, the patient, sitting upon a chair, is requested to place his leg over an ordinary wash-hand basin, so that the heel rests upon another chair. By means of a spray apparatus sulphurous acid is then freely applied to the affected parts, which are to be thoroughly soaked in the acid. This done, about half a pint of boiling water is poured into the wash-hand basin, containing two teaspoonfuls of carbolic acid, and the requisite mixture effected by stirring. The first strip of plaster is now rapidly run through the hot carbolized water two or three times, backwards and forwards, and immediately applied. It is necessary to begin about two or three inches below the lowest diseased part of the skin. The middle of the strip being adjusted to the back of the leg, the ends are brought forwards, and after being crossed, are carefully laid down on the skin. Great care should be taken to avoid undue pressure. Gentle and evenly distributed support, without compression, should be the operator's aim. The edge of the next strip of plaster is made to overlap about one half the width of the first, and then similarly applied, and the others in like manner to the highest. The plasters should cease two or three inches above the highest diseased portion of skin. By means of a towel all excessive moisture of the plasters is now removed. Finally a cotton bandage, two and a half inches broad by seven yards long, is carefully and evenly adjusted,

without undue compression, from the root of the toes to the knee. The kind of plaster I find most useful is the ordinary emplastrum adhesivum spread on brown holland. The patient is now instructed to return that day week for the second dressing, and, in the meantime, endeavour to resist any inclination to interfere with the coverings as applied. In exceptional cases pain, or a sort of neuralgia, over the site of ulcer occurs. When this is bearable it is always best to do nothing, but when very severe much relief is felt by the patient removing the cotton bandage and pouring cold water from a jug upon the plaster strips, as recommended by Baynton. Of course the bandage is to be immediately re-applied, after drying the plasters with a towel. After two or three weekly dressings there appear, in some cases, crops of watery vesicles on portions of the healthy skin. On bursting, these leave small abrasions which at times assume an alarmingly angry look. However, they are not at all important, and are always relieved, and cured, by the sulphurous acid spray. I have regarded them as due either to stimulation of the plasters, or the confinement of normal perspiration. During the intervals of treatment patients should be enjoined to resume their ordinary habits of life, and work, even in spite of pain or stiffness of the limb. Muscular action is of course an important aid to the circulation of blood and lymph through a limb, and is to be encouraged accordingly.

Now in the vast majority of ulcers of the leg no other treatment is at all needed, in fact the management of few other ailments is so thoroughly stereotyped. The preliminary treatment so continually recommended is absolute waste of time; and the endless paraphernalia of lotions, ointments, touchings with caustic, etc., etc., may be put aside. Though the cases requiring skin-grafting must be few indeed, as I have never come across any, there would be no difficulty in combining the latter with the proposed method, and thus getting rid of the necessity of laying up the limb. I would further add that as far as Baynton's strapping, used antiseptically, is concerned, all classifications of ulcers—such as irritable, inflamed, indolent, and varicose—are unnecessary, and likely to mislead, seeing that all are to be treated alike. In my experience the most painful varieties are those where the ulcers are found in the folds of skin around the ankle joint, the veins being tortuous and varicose. The latter feel like masses of thread upon which beads have been strung at intervals. In such cases it may sometimes be advisable to pad a sharp point, or pack an angular cavity, with cotton wool, in the act of applying the plaster strap. "The most irritable ulcer may be strapped if care be used and compression avoided. The horny edges of 'callous' varieties soon soften down and disappear without recourse to so dangerous an excitant as blistering, which may easily set up unmanageable inflammation" (see paper, *B.M.J.*, May 31st, 1873).

When the manufacture of India-rubber had reached such a state of perfection as to allow of the introduction of Martin's bandages, I quite thought that a panacea for ulcers of the leg had been found. The fenestrated variety of bandage, especially, seemed most likely to be successful. It was, therefore, disappointing in practice to discover such serious drawbacks in efficiency that I was obliged to abandon this mode of treatment in favour of my own. The flow of perspiration in many cases seemed intensely excited by the contact of India-rubber with the skin; whilst in others, heat and irritation became so unbearable that patients were refractory and lost confidence in the remedy. Success, where attainable, was, moreover, decidedly quali-

fied by the trouble and inconvenience experienced in the removal and washing of the bandage every night and its re-application the following morning before rising. In the avoidance of such frequent interruptions of treatment will be found one of the great advantages of the method I now advocate.

With regard to the causes of these ailments, I am far from agreeing with many of the opinions expressed in the *British Medical Journal* "Reports." No doubt varicose veins decidedly predispose; but they are common among the rich and well-fed as well as the neglected poor. In many individuals they are the outcome of hereditary weakness. It is very questionable whether the privations, and the degraded and intemperate habits of our poor, are related as causes so much as the various toilsome avocations which require the worker to spend many hours daily in the erect position. Not only under these circumstances is the force of gravity constantly resisting that of the heart, but the latter obtains little or no aid towards the venous and lymph circulation by the due exercise of the leg muscles, which are comparatively inactive for long periods. Many employments also require the individual to carry heavy weights, or to rest the latter, temporarily, upon some part of the upper limb, thus materially obstructing circulation.

I would further suggest that the treatment now recommended may prove of great value in certain congestive conditions of a limb other than those mentioned, where no ulceration is present, and where support to the blood-circulation is not so obviously indicated. As an illustration I would refer to a case of erythema nodosum which I saw recently. The patient was a lady about fifty years of age, of highly neurotic temperament, but otherwise in good health. She had suffered previously from several attacks of this troublesome and painful ailment, which had been somewhat puzzling to the doctors she had consulted, who had on each occasion found much difficulty in effecting a cure. The eruption, as seen by me, extended down the inner side of the right leg from a little below the knee to near the ankle. The tubercular swellings were very painful, and there were much heat and redness of skin. I quite expected to cure the case with iron tonics and arsenic, but they proved of little avail. Whilst pondering over my want of success it occurred to me that as the vaso-motors of the affected area were evidently in a relaxed state, it might be a useful stimulus to the trophic nerve centres to strap and bandage the limb. This was accordingly done. The first dressing immediately gave comfort to the patient and enabled her to walk about again. When it was removed, at the end of ten days, there was such evident all-round improvement that the applications were renewed. No other treatment was needed, and the second dressing cured the case. Whether such a method would succeed in other instances of erythema nodosum I cannot say, but the plan is worth a trial. It might prove most valuable in the treatment of servant girls, for example, if it enabled them to continue their duties whilst the constitutional depression and anæmia usually present were being removed by suitable medicines.

After a chronic ulcer of the leg has been cured it is necessary in many cases to ensure some efficient and permanent support to the circulation through the affected limb, lest a return of the ulceration should occur. This only applies where the regularity of the blood-flow has been seriously weakened by embolic formations, varicose veins, etc. I always take some pains in pointing out the reasons why such patients should constantly wear a well-fitting

elastic stocking, or bandage, and not imagine that a method of cure which has only been applied over a few weeks can remove a permanent or life-long infirmity. Where ordinary care is taken I believe the relapses are few and the intervals of time long. Only last year a lady consulted me whom I had treated for severe varicose ulcer fifteen years ago. During that long lapse of time she had remained perfectly well till within a few weeks of my seeing her again. She had latterly become very careless about bandaging, and also neglectful of her general health. One dressing was, however, all that was found necessary to put her right again.

I shall be glad if this plan of treatment is found as useful in the practice of others as it has been in my own. More especially should I like to see some similar method adopted in the hospital out-patient department, where it would certainly be a boon to many humble sufferers, and would send them "on their way rejoicing."

TWO SUCCESSFUL CASES OF LAPARATOMY FOR SUPPURATIVE PERITONITIS.

BY GEORGE ELDER, M.D.,

SURGEON TO THE SAMARITAN HOSPITAL FOR WOMEN, NOTTINGHAM.

In the *Provincial Medical Journal* for September, 1886, I gave the particulars of a case in which, for an encysted peritoneal abscess, abdominal section and drainage were followed by a successful result, and although since then several laparatomies have been performed by me for the relief of various serious conditions, due to chronic peritonitis, such, for example, as intestinal adhesions, intestinal obstruction, etc.; still it is only within the past few months that further illustrations of suppurative peritonitis demanding surgical interference have enabled me to supplement my original article. The first of the cases, singularly enough, occurred in the practice of Dr. Burnie, under whom also the former case had been, and the second was seen by me, with Dr. Mutch. Briefly, their records run as follows:

Case 1.—Miss F—, æt. thirty-nine years, was first seen by Dr. Burnie, about twelve years ago. There was a history of a fall a year before, since which she had never been free from pain in the lower third of the abdomen. There was at this time a decided ante flexion of the uterus, for which a cradle pessary was placed in position. From then until August, 1887, Dr. Burnie lost sight of her, when she again came under his treatment for persistent pain, with frequent acute exacerbations, over the cæcal region, accompanied with intestinal disturbance, and occasional rises in temperature. There was an area of exquisite tenderness over the cæcum, with some degree of fulness. The ante flexion, for which the patient before time had been treated, still existed, and there was also an intra-mural myoma, which for some time past had caused severe, prolonged, and too frequent menstrual losses. There was also a constant inter-menstrual, irritative vaginal drainage. For months there had been a progressive depreciation in health. Three months' absolute rest in bed, and everything short of surgical interference was carefully tried by Dr. Burnie without relieving her condition, and, after consultation, she was admitted into the Samaritan Hospital for Women, for an exploratory operation.

On December 8th, abdominal section through the median line was performed, and vent given to a large encysted perityphlitic abscess of a distinctly fæcal odour.

On account of the menorrhagia and pain, brought about by the myoma, the uterine appendages were removed at the same time. After washing out the cavity with warm water, a drainage tube was inserted, and the parietes brought together by silk sutures. Beyond a little distension on the second day, the after-progress of the case presented no unusual features: the bowels were well moved on the 11th, and for the first few days, when the discharge was profuse and offensive, the contents of the tube were withdrawn every two hours, and irrigation with a 1-in-50 boro-glyceride solution used. For five weeks after the operation, a glass drainage tube was employed, and then a rubber one substituted. For three weeks longer this was kept in position, shortening it from time to time as thought desirable, when it was removed. On February 9th, the patient who had been getting about in the hospital for over a week, went out well, with a perfectly healed and firm cicatrix.

Case 2.—Mrs. T—, æt. twenty-six years, seen with Dr. Mutch, on November 22nd, 1887. Prior to puberty patient's health had been good; menstruation began at sixteen, and was regular for ten months, when her health failed; the function being then in abeyance for a year. Up till twenty it was again regular, profuse, and, at times, very painful. From twenty to twenty-one, patient was what she called "sensibly deranged;" menstruation again ceased, and during this period a somewhat obscure history of a yellow vaginal discharge, with heat of the parts, and urethral irritation, is elicited. From twenty-one up till within a few months of the present time, the menstrual function has been regular, but been lessening in amount, and accompanied with increasing local disturbance. Since twenty-one she has had one or two pelvic inflammations yearly, with symptoms of threatened intestinal obstruction. Two years ago she got married; coitus has always been painful, so much so that, for several months before Dr. Mutch was called in, it had not been attempted. From last October, patient felt very ill, and could, with great difficulty on account of backache and pain in the right side, get about. This culminated in her being laid up entirely a fortnight ago, with "inflammation of bowels and stoppage." Under appropriate treatment and rest, the urgency of the symptoms subsided until the morning of the 22nd, when she had a relapse. On the same evening Dr. Mutch and I saw her together, when we found the lower abdomen slightly distended, tympanitic, and very sensitive to touch, especially in the right iliac region. The temperature had never been above 100°; yet the gravity of the case was apparent from the general prostration of the patient, and the drawn, anxious expression.

Vaginal examination revealed retroversion of the uterus, mortared in an exudative mass, including the appendages. Abdominal section being agreed upon, the operation was performed at the Samaritan Hospital, on the morning of the 24th. An incision having been made in middle line, easily broken down adhesions were found glueing the intestines to the parietal peritoneum, and to each other. There were also utero-intestinal adhesions, especially on right side. The peritoneum was thickened, deeply injected, and so also were the bowels within sight, and dull. When the separation of the coils of intestine from each other, and the uterus had been effected, a considerable quantity of sero-purulent fluid welled up from the pelvic cavity. At this point the condition of the uterus and its appendages was noted, and so matted together

were they by inflammatory deposit, that with difficulty could they be differentiated. From the firmness and closeness of these adhesions, it was not thought expedient to attempt their removal. A boro-glyceride solution was used to wash out the cavity, and the parietes were brought together as before, and a drainage tube inserted into Douglas's pouch. Drainage was employed till the beginning of the third day, and from the time of the operation till a week after, when the track of one or two of the sutures suppurred and raised it; the temperature was practically normal. The convalescence of the patient was somewhat retarded by this, but on January 4th she was dismissed well.

February 25th.—I have seen patient at home to-day, and she expresses herself as better than she has been for nearly a year. Her only complaint is of some little trouble in bringing about regularity of the bowels.

Remarks: Mr. Treves, at a meeting of the Royal Medical and Chirurgical Society (*vide Lancet*, vol. 1, 1888, p. 322), read a paper on "Relapsing Typhlitis treated by Abdominal Section," based upon a successful case in which he had removed the diseased appendix vermiformis. Doubtless perforative ulceration of the appendix, arising from intestinal concretions, or the impaction of foreign bodies, is in the majority of cases at the bottom of perityphlitic trouble; but where, as in my case, the inflammation had eventuated in a circumscribed peritoneal abscess, it is not wise, I think, to interfere with the appendix, unless obviously diseased, especially as such interference might break down adhesions which had effectually healed the formerly-ruptured organ.

Nothing short of incision and drainage would have benefited the patient, and had rupture taken place into the general cavity of the peritoneum, death would of necessity have quickly followed.

With regard to the second case, it is an instance of general peritonitis, arising from the extension of tubal inflammatory mischief, probably gonorrhoeal in its origin. The virulence of the process is shown by the nature of the effusion; the rapidity and extensive character of the adhesions, and the disproportion which existed between the local symptoms, and the grave constitutional disturbance. If such cases are not soon relieved by operation, general toxæmia quickly supervenes. If it had been possible, without undue violence and risk to the patient's life, to have removed the uterine appendages, a more satisfactory result so far as the future of the case is concerned, would have been attained. Apart altogether from its interest as bearing upon treatment, the conditions found throw a flood of light upon the genesis of intestinal obstruction. It is well known that acute peritonitis by paresis of the bowel brings in its train obstruction, which, if overcome, in many cases wards off impending death. The adhesions caused by peritonitis may, unless thinned and ultimately broken down whilst in their recent state, by intestinal movement; by constricting the lumen of the gut, or forming loops under which coils of intestine may become strangulated; become a constant cause of pain and illhealth, as well as the first step towards a fatal illness. Bearing this in mind, and especially with the light thrown upon the far-reaching and serious effects of local and general peritonitis, as evinced in operations for its chronic forms and *post-mortem* examinations, the time is doubtless within measurable distance when abdominal section in these cases will come into more frequent and early requisition.

OVARIOTOMY IN AGED PEOPLE.

By FANCOURT BARNES, M.D., M.R.C.P.,

VICE-PRESIDENT OF THE BRITISH GYNÆCOLOGICAL SOCIETY; PHYSICIAN TO THE CHELSEA HOSPITAL FOR WOMEN; SENIOR PHYSICIAN TO THE BRITISH LYING-IN HOSPITAL AND THE ROYAL MATERNITY CHARITY.

AMONG the various abdominal sections occurring in my practice during the year 1886 were three cases of cystic disease of the ovary in women, aged sixty-five, seventy, and sixty-seven respectively.

Case 1.—M. A. R.—, æt. sixty-five; married thirty-one years; menstruation ceased fourteen years ago, iv. para; last pregnancy twenty-four years ago. History: Six years ago noticed the abdomen began to swell. During the last four years abdominal pain has increased, the abdomen has become enlarged, and she has been unable to attend to her duties. On examination, the abdomen was found to be extremely distended by a symmetrical fluctuating tumour, reaching into the epigastrium and pressing on the diaphragm as to cause considerable dyspnœa. May 13th.—The patient was placed under ether and the usual incision made through the abdominal walls. Three large cysts were successively evacuated by the trocar, and thirty-five fluid pints evacuated. The pedicle was so broad that it was necessary to transfix and tie it in two places. The abdomen was then closed with silver sutures. The patient recovered without any unfavourable symptom, but as she was much emaciated it was deemed advisable to place her on a water-bed. The pulse and temperature were normal throughout.

Case 2.—R. H.—, æt. seventy; married, vi. para. About eighteen months ago she noticed that the abdomen was gradually increasing, and that during the last three months it had rapidly become larger. She is extremely emaciated. The abdomen measured forty inches round the umbilicus. The distance from the umbilicus to the symphysis pubis measured eleven and a half inches. Her general condition was far from satisfactory. She vomited after every meal. Her breathing was carried on with such difficulty that she had to be supported in bed. Examination of the heart revealed a loud systolic murmur. Bronchitic rales were heard over the whole of the chest. April 5th.—The patient having been anaesthetised by chloroform, an incision of five and a half inches was made through the abdominal wall. The cyst was found to be adherent throughout to the abdominal wall. The adhesions having been broken down, the cyst was evacuated. On drawing out the tumour the uterus followed it, and, as might be expected in a woman of her age, was atrophied, and attenuated to such a degree that it might easily have been transfixed and secured as part of the pedicle. The pedicle was then transfixed and tied, and the abdomen closed. A poultice was applied to the chest the same evening. April 6th.—As she complained of much pain in the lower part of the back, she was placed on a water-bed. April 10th.—The wound was dressed with iodoform, and two sutures removed. April 13th.—The remaining four sutures removed. April 14th.—Loud bronchitic rales heard over both lungs. April 28th.—Wound healed. May 8th.—Patient out of bed and doing well.

Case 3.—B. T.—, æt. sixty-three; married forty years, x. para; last catamenia twelve years ago. She noticed a swelling in the abdomen two years ago. She was tapped ten months before admission into the hospital. There was a systolic murmur of the heart. The abdomen was distended from the symphysis pubis to the sternum. The veins over the abdomen were distended, and there was

œdema of the walls. She measured forty-six inches round the umbilicus. On September 3rd, the abdomen was opened, and the cyst was found to be firmly adherent throughout the whole of its anterior surfaces to the abdominal parietes. These adhesions having been stripped from the abdominal wall, the trocar was inserted, the tumour removed, and pedicle tied with silk ligature. The pulse and temperature remained normal until September 11th, when the sutures were removed and the wound found to be firmly united. The only difficulty arising, being a suspicious looking red surface over the lower part of the sacrum. She was placed on a water-bed, and directions were given that she should be turned over from side to side at regular intervals. On the 2nd October, she left the hospital perfectly well.

My chief object in recording the above cases is to draw attention to what I believe to be the most important factor in the management of aged people in ovariectomy, and that is, a sufficient amount of movement in bed. The ordinary practice is to keep the patient motionless on her back during, at least, the first five or six days after an operation. It is difficult enough for the young and fairly healthy subject to pass through this ordeal without developing bed sores or hypostatic congestions. As a matter of fact, I have seen retroversion of the uterus produced in this way in a young woman on whom I had performed perinæorrhaphy. It has for some time past been my custom to see that the patients are not kept fixed in this way on their backs. In all of the above cases I took particular pains to see that the patients were carefully moved first on to one side and then on to the other, so that they were not continuously lying in the dorsal position. In fact, as far as my experience goes, the danger from bed sores is the only complication to be dreaded after ovariectomy in aged people. It is obvious that the only way of avoiding this is to give the patient change of position from time to time.

CHANGE OF AIR AS A THERAPEUTIC AGENT.

BY ALFRED J. H. CRESPI.

SIR JAMES PAGET, in the Fourteenth Volume of the *Nineteenth Century Review*, has dealt in his characteristically thoughtful, suggestive manner with "Recreation." I have this morning been reading that paper for the second or third time, and can see nothing to add to it or to qualify. Sir James is a man whom any profession might well be proud of, *facile princeps* in his own line, and devoted to it; while, at the same time, finding much interest in other pursuits, and, what is comparatively rare in medical circles, with a charming facility for conveying to the non-medical mind, in the most graceful and appropriate language, the subtlest truths. A subject which an ordinary man only with difficulty understands, and which he cannot for the life of him explain to others without losing himself in a perfect fog, Sir James Paget handles with the mastery of a genius, and presents in such attractive colours that he invests it with a charm that hardly seemed to belong to it. To his popular and practical paper on "Recreation" nothing can be added. But I want in equally general language to say something—not on change of occupation for the hard-worked business man—but on change of scene as a means of restoring the sick to health.

No subject is more commonly handled in hospital lectures. Not a day passes that the student's attention is not directed to the value and importance of change of air—

that is to say, of scene, surrounding water, and residence; and the student starts in practice convinced that change is a most potent and infallible agent for good, and when it disappoints him, as it too often does, he regards the result as exceptional and almost inexplicable. I used to have profound faith in change, and though my own narrow circumstances did not admit of my ever having a change, or, indeed, of getting that recreation which Sir James Paget so wisely and warmly recommends, I used to advise it to others, and it was a long time before I found out how uncertain and disappointing a remedy it is. In a large majority of cases change of air does not benefit the invalid and the convalescent. The trouble, expense, and worry of getting the change are not repaid by improved health, and the medical attendant is mortified at the result—one for which even twenty years of assiduous practice do not always prepare him.

Change of air for the over-worked town resident is invaluable: it may be the one delightful month of the year that cheers him in anticipation and comforts him in recollection. The man who cannot afford a change, or at any rate, a change with an easy mind, knows only half the pleasure of existence. Perhaps, however, I ascribe more potency and enjoyment to change than it deserves. It may be that never having been able, since I commenced my career as a student, to leave home for a single week with a fair command of money, and merely to see the world, I invest it with greater attractions than I should do had circumstances been more favourable. In my own case, I commence my work soon after eight, and go on till midnight, rarely compassing all I want to get through in that time, and having to use a large part of the Sunday to keep pace with the demands and urgent calls upon me. All that Sir James Paget says of recreation—its pleasures, advantages, and value—I should endorse. To leave home for a month, even for a week, is a treat that I have not enjoyed for many years. With an easy mind, just to devote myself to seeing paintings, majestic buildings, interesting foreign cities, or revelling in the exquisite scenery, which no country offers in greater variety than ours, would be a memorable episode in my life. But that must be left to the more fortunate members of the profession, who, commencing their career with the command of large resources, or succeeding to a well-established and lucrative position, have not had to think twice before spending a shilling, and to those opulent commercial magnates who grind life, hope, and strength out of their unhappy white slaves, and while complaining that they are losing money fast, contrive, though beginning with nothing, to retire, after thirty years of comfort and affluence, on an ample fortune to rust away the remainder of their days.

Change of air as a therapeutic agent requires care, and a few simple rules may be of value. It is not enough that the patient should be getting well, and that, in theory, complete change would be beneficial. The first great consideration is—can he leave home with a quiet mind, determined to get good and to return well? Very often, when change is proposed, it is eagerly accepted. Great expense is incurred, and much trouble taken, and the sufferer goes away full of hope. At first the reports are most encouraging; then, improvement halts; and, at last, when the change is over, and the invalid is at home again, no permanent good has resulted. We are all familiar with the death-bed scene of poor Oliver Goldsmith—that good-natured, self-indulgent, dissipated man. Dr. Turten said to him towards the end, "Your pulse is in greater

disorder than it should be from the degree of fever you have. Is your mind at rest?" "No, it is not," answered the dying poet. *There* was the secret—the mind was not at ease, and no change of air could have done much for the careless fellow, so genial, in spite of his many faults, whom Johnson and Burke loved, and for whom Reynolds, when he heard the news of his death, actually laid down his pencil, and left his studio for the day, a mark of mental disturbance rare in the great painter, who could see nothing remarkable, or, indeed, calling for comment, in the masterpieces of mediæval art.

Everyone must have been struck by the great contrast between children and grown-up convalescents in the matter of change. Take a child of twelve or fourteen, with the world untried, unknown, all before him to choose his place of rest. The railway journey, so wearisome to his senior, delights him; every turn in the road opens up an interminable vista of beauties. A smoky manufacturing town, seen in the sombre atmosphere of an English December or January, is as fascinating as the City of Flowers to the scholar and the art connoisseur. A children's party gives him pleasure keen as an international gathering to the weary man of the world. In short, a few humdrum weeks in a most commonplace house are an event; he has no anxiety lest his work is being neglected; he does not fear the rapidly accumulating heap of bills; he does not fret and fume over the loss of precious time; he is not worried by the start which his rivals will get over him. To him it is change in the best sense of the word; he sleeps, eats, drinks better, his heart gets stronger, his pulse quickens, his colour rises. How sorry he is when obliged to return home; how ardently he longs for another such change. Thirty years later, how different all is! The train may whirl him through the loveliest scenes of nature, kind hands may welcome, gentle voices may cheer, all may be done to make the change acceptable and soothing, but in vain. The thoughts return, in spite of himself, to the familiar scenes of life. He has changed his surroundings, but not himself. *Quis exsul patriæ se quoque fugit?*

First and foremost, to get benefit from change the thoughts must not be preoccupied, distracted with home cares. How often have sufferers said to me, when I have urged change, that they could not leave home in comfort: the children, the servants, the household cares, would still be with them. Cumbered with many cares, would sum up the lives of many otherwise estimable women. Great discretion is called for in such instances before recommending change; and with rare exceptions, it is far better clearly to point out that change, to be attended with advantage, must be undertaken with a quiet mind and every expectation of good. Nor is the medical attendant justified in urging poor people to face the serious expense of removing the whole family, so that the invalid should take the cares of daily life with him. The pleasure of the change is, under such conditions, soon over, and there comes the daily increasing anxiety of making both ends meet, and the stinting and contriving to defray the expense. A few weeks of not unmixed pleasure are followed by months of straitened circumstances and painful, grinding economy. England may be the richest country under the sun, though I have serious doubts on that score, notwithstanding Archdeacon Farrar's recent letter in the *Times*. But the exigencies of society and fashion are rigorous, and poor middle-class families seldom feel that they dare rent a small country cottage for a few months, and live cheaply

and economically. Change, if attempted at all, must be carried out with due regard to the opinions of their neighbours and of their class in life, and that means a large outlay that cannot possibly, in too many instances, be faced with prudence.

A large proportion of the persons requiring thorough change consists of middle-aged, middle-class sufferers, who cannot leave their cares behind them, and who are, moreover, far too greatly preoccupied to make removal from home beneficial; and here the medical attendant should frankly point out the difficulties, and should very rarely urge change. People are not always proof against argument, and they will sometimes thank their adviser for his candour and sympathy, and patiently remaining at home, will get far more good there.

Change of air should not be recklessly prescribed for people suffering from chronic and incurable disease, like cancer, consumption, and renal affections in the later stages. The doctor is tempted to promise benefits, which the result will not justify. The patient leaves home, hoping for permanent good, which he cannot possibly obtain. For the first few days he is perhaps better, while his anxious friends at home are in a state of suspense. At last the sufferer gets too ill to bear the return journey, or is in such serious danger that his friends have to be hastily summoned, often at extreme inconvenience. Surely there is great want of wise forethought on the doctor's part here. No medical attendant has any right to send from home dying patients, buoying them up with false hopes, subjecting them to great inconvenience and, perhaps, serious expense, and exposing some strange practitioner to groundless suspicion that he has hastened death by unskilful treatment or inexperience. Candour on the doctor's part will be best for the client, and most honourable to the medical attendant, and he will be acting as he would wish to be done by.

Cases are not infrequent of well-to-do invalids, often self-indulgent, with few cares, and no regard for anyone but themselves. After a time they weary of their surroundings and tire of their doctor, and he, poor fellow! having treated them for ills of nerves and stomach, for sleeplessness and indigestion, for kidney disease and lung mischief, feeble heart and relaxed sore throat; having rung the changes on half the remedies in the "Pharmacopœia," and having in return earned and deserved little thanks, he, I say, begins to think that change of air would be beneficial, and could not possibly do harm. By this time usually the interesting client has lost confidence in the attendant, who cannot do the impossible, and cure diseases that do not exist, improve habits radically bad, and give a thankful, considerate heart. The least severe criticism passed upon him will be that he is an old woman—a curious sting seems to lurk in those words, by the way—who does not understand the sufferer's case. Here, then, providing the client desires it, change may be recommended. But beware of urging change where it is not desired, for depend upon it, good will not result. Moreover, the doctor must not allow his own partiality for certain places to influence him in displaying their attractions before his unwilling clients. However unsuitable the spot chosen may be, or seem to be, the practitioner should feel very certain of his position before venturing to remonstrate, or suggesting some other. If the client has set his mind upon the least prepossessing place in Christendom, he will get more good than from any other. He has reasons, whims, fancies, that weigh with him, and into which strangers cannot enter,

Taking it as a whole, regarding the matter in the light of a philosopher and of an experienced practitioner, I contend that change of air is a less potent factor for good, a less reliable therapeutic agent than commonly supposed, and that it needs using with consummate care and discretion, always following the patient's tastes, and always having due regard to his circumstances. In many cases change is inexpedient; in some, most injurious; in others, it should only be permitted after a long and confidential interview with client and friends, and after the latter have been carefully prepared for the probable results.

It is little to the point that the medical attendant has taken the trouble to make himself thoroughly acquainted with the circumstances and peculiarities of a place, and only recommends one which he knows. Clients will rarely submit to dictation, and no more ungrateful duty falls to the doctor's lot than to give sound and good advice on such points. What he most approves his clients may regard with the greatest disfavour. Accommodation that to him seems unexceptionable, will to them appear just what it should not be. Far better, far easier, to weigh with discrimination all the surroundings of the case—the patient's age, idiosyncrasies, pursuits, temperament, and means; and then, if deciding to advise change, to do so with great caution, following the client's leading, seldom, indeed, pretending to dictate to him. You may put the sufferer in conditions favourable to recovery, but his broken constitution may make improvement impossible, or his unfortunate temper and peculiar tastes may nullify the good he ought to get, and if things go wrong, the doctor will not soon hear the last of it, if he escapes being blamed for being the primary cause of all the mischief.

There remains a large part of the subject to deal with, that for its proper treatment requires a volume—the selection of a place for the invalid whom circumstances justify in leaving home. In summer, or say from the beginning of May to the end of September or the beginning of October, the south and south-west can be fairly counted upon to offer warmth and a good deal of sunlight, and the midland and northern districts are not much behind, from the last day of May to the last of August, in all the requirements for out-door exercise, except in the far smaller amount of sunlight which even at that season they enjoy. In winter, matters are far otherwise. North, south, east, and west, clouds abound, and the cold is seldom bracing or pleasant. Little indeed can be gained by sending a patient from Birmingham or Manchester to Bournemouth or Ilfracombe, that will compensate for the expense of the change and the loss of the comforts of home. Medical advisers are often wanting in judgment in their recommendations. What possible use can there be in sending an asthmatic invalid to Malvern, with its steep hills? Or what is gained by advising a town bird—afraid of a drop of rain, and accustomed to cabs, clean crossings, and dry pavements—to go to a small western seaside watering place in winter, where, as a clergyman once said to me, he had had three weeks' constant rain, and never could venture out for wind and fog? Nor should the doctor descant warmly on the pleasures of the place he recommends. Let him observe a wise reticence. His associations may be all he can desire, but others may feel differently, and the scenes that so much impressed him may not arouse similar interest in them. And yet, in spite of drawbacks, change, with certain limitations, is an invaluable adjunct to medical treatment,

FROM GENERATION TO GENERATION: A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.,
F.R.S.L., ETC.

(Continued from page 102.)

Hepatic Diseases.—The foregoing arguments as to the influence of heredity in diseases and disorders of the kidneys and chylo-poietic viscera, apply with equal force, for obvious reasons, to diseases and disorders of the liver. I need not here recapitulate them in any detail. Of the degenerative diseases of the liver—cancer, cirrhosis, amyloid degeneration, fatty infiltration, etc., it may be safely said, irrespective of their proximate causation, that, at least the majority, if not all of them, are dependent upon constitutional conditions, and that a predisposition to each of these, either in the person of the afflicted parent or of his children, is more or less, but almost invariably, inherited. Let us briefly consider these diseases of the liver in the above-mentioned order, and with especial reference as to how they are affected by heredity. With regard to diseases of the liver in general, Frerichs in his great work remarks that "the data heretofore established are not sufficient to secure to heredity a positive influence." That he was at least mistaken with regard to hepatic cancer, there cannot be the least doubt; and if in one case, why not in all? It is only fair to assume, that at the time this distinguished and original writer published his *magnum opus* (1858), the subject of heredity in relation to disease was comparatively little understood, and that the mind of the author had not been especially directed towards its consideration. It has long been generally acknowledged that the heredity of cancer is well-established, and "that which applies to cancer, in general, self-evidently and as a matter of experience, equally applies to cancer of individual organs."¹ Statistics are not very reliable as a rule, but even these prove without a doubt that cancer is hereditary. Thus of 1127 cases reported by Paget, Cooke, Sibley, Lebert, Lafond, Hess, Moore, and others, 192, or 17 per cent. were found to have been inherited; and I have already elsewhere recorded a case in the practise of the late Dr. G. H. Barlow, in which a lady was the fifth victim of cancer of the liver in two generations.

In such a case as the last one cannot fail to be struck with the hereditariness of cancer; but it should never be forgotten that, although diseases and predispositions, being subjected to the influences of other diseases and predispositions, are not unfrequently reproduced hereditarily in a modified form, yet that the heritable influence always exists in one form or another. Cirrhosis of the liver offers a case in point. What are its causes? (1) Spirit drinking, a predisposition to which is undoubtedly heritable; and who can say that a predisposition to its effects corporeally is not also transmissible? (2) Syphilis; can there be any doubt as to the inheritance of this disease? (3) Malaria, as we have seen in the consideration of the malarial diathesis, is potently hereditary. The other known causes of cirrhosis of the liver are subsidiary, and need not here be considered. Here then we have an affection, the three main causes of which are indubitably subject to heredity, and however diverse in their nature, yet tend to produce a well-known disease of the liver! Here we have an example of the manifold and complex influences of heredity on the human system in relation with its diseases, and it should always be remembered that

¹ Leichtenstern.

there are many cases in which, although like cannot be said to produce like, yet the influence of heredity is potent and effective. When alluding to cirrhosis of the kidneys, I stated that it was frequently observed as part of a constitutional condition characterised by fibrotic changes in vessels and organs; these observations are, however, still *sub judice*, so I shall not insist upon their accuracy, but I have, at least, shown that the causes of cirrhosis of the liver are mainly heritable, and if so, I cannot see why their effects should not be so also. If a predisposition to allied pathological changes or conditions is inherited, as it unquestionably is, I fail to recognise the mode of reasoning which would exclude cirrhosis of the liver—or at least a predisposition to it—from the same category.

Amyloid degeneration, whether of kidneys, liver, or other organ, never appears as a primary affection, but as the result of a pre-existing general cachexia, induced by various morbid conditions usually associated with prolonged suppuration, ulceration of bones and joints, also of soft parts (as in empyema), or with chronic pulmonary phthisis, constitutional syphilis, or other chronic constitutional diseases. Like most other constitutional conditions, the cachexia, however induced, may be transmitted, whether associated with amyloid degeneration or not; and what is still more to the point, according to Rokitsky and other observers, amyloid disease, and especially amyloid disease of liver, has been known to occur actually as a congenital condition in cases of hereditary syphilis. There is therefore no reason why a predisposition to amyloid disease of liver or other organs should not be inherited. If not a product of the scrofulous diathesis, amyloid disease is certainly the resultant of a pre-existing condition closely allied to it.

I may dismiss the consideration of fatty infiltration, or fatty degeneration of the liver, in a few words. Both may be regarded as modifications of the natural fat-forming process; in the first case being brought to the liver-cells with the blood; in the second, originating in the interior of the liver-cells themselves, from the albumen belonging to them. The first partakes of the nature of that general condition which we term obesity or corpulence, a predisposition or tendency to which is handed down from one generation to another; the second partakes of the nature of metamorphosis—fatty atrophy of the cells, resulting from the non-restoration of albumen expended in the preparation of fat. This latter condition is also hereditary, and may involve other organs than the liver, as the heart, etc.

Passing now from degenerative diseases to functional derangements of the liver, I may here briefly allude to cholelithiasis or gall-stones, icterus or jaundice, hepatic congestion, and "biliousness," which are all more or less hereditary. Fauconneau-Dufresne asserts that gall-stones are frequently hereditary, basing his assertion on the experience of the bath physicians at Vichy, who have so many opportunities of observing every kind of liver disease. Be this as it may, we cannot say that gall-stones, or a predisposition to them, are not hereditary, simply because from our inexperience or ignorance we cannot say whether they are or are not. If the views enunciated in the foregoing pages have anything to support them, we should have no difficulty in understanding why they should be hereditary, like other morbid processes, and we can only trust that time and experience will ultimately clear the way from every doubt, either one way or the other. Icterus or jaundice is also hereditary; thus Kerkring mentions an example of a woman afflicted

with jaundice, being delivered in the eighth month of her pregnancy of a still-born child, whose very bones had a yellow colour. This case seems to support the views of such pathologists as Hartmann, Conradi, and others, who believe that in many cases, instead of a mere predisposition communicated by the parents to their children, the disease itself is inherited; and they appeal to experience, by which it is proved, as they allege, that many children are born with diseases under which their parents suffered. We must acknowledge that deformities generally, and especially anomalies in the external parts, as varus, sex-digitism, also diseases of the eye, especially cataract, if inherited are brought into the world with the children; but, on the other hand, in the majority of so-called internal diseases, a predisposition only is more frequently inherited. Probably the true explanation may be found in the following circumstances—viz., that with respect to the majority of internal diseases, it often depends upon the more or less high stage to which the disease has risen in the parents, whether they communicate to their children merely a predisposition, or the disease itself. How it happens, however, that sometimes the predisposition only, and sometimes the disease itself, is communicated, must, like many other questions, for the present remain unanswered. In addition to the case of hereditary jaundice observed by Kerkring, many other observers have seen interesting cases of women, afflicted during their pregnancy with icterus, having been delivered of jaundiced children. No less scarce are the cases where all the members of a family have been attacked by jaundice at the same age; and an especially remarkable one is described by Boerhaave.¹

That there is an especial predisposition on the part of the patient to the hepatic congestion induced partially by dietetic irregularities, peculiar to middle life, cannot be doubted, and if we consider how different individuals are differently affected by free indulgence in nutritious diet and irritative articles of food, whilst at the same time leading a sedentary and inactive life, the reason is not far to seek, for as individuals differ from each other in every respect, physiologically, psychologically, and pathologically, so must each individual differ from every other in his inherited tendencies. How else can we explain the reason why amongst a set of freely-living indolent men one will suffer, in consequence of his mode of life, from hepatic congestion, another from obstruction, another from constipation, another from hæmorrhoids, etc., while others remain free from any such disorders? Apparently the mode of life has much to do with the production of such conditions, but primarily, the inherited predisposition influencing every organ and tissue of different individuals in various ways and degrees, alike in health and disease, constitute the real reason. Virchow has already demonstrated very considerable individual differences in the conditions of the arterial walls: why then should the occurrence or non-occurrence of the above-mentioned conditions under precisely similar circumstances not be accounted for by individual differences in the condition of the walls of the vessels belonging to the portal system; nay, more, to individual differences in the development, nutrition, and innervation of the muscular tissue of the intestines? These relative individual differences of bone, tissue, cell, organ, membrane, and vessels, which are admitted by all competent authorities, really form the foundation of all sound views in pathology, and the more

¹ Steinau.

they are recognised and appreciated, the more will the art of medicine acquire scientific exactitude and increased usefulness to humanity. In the words of Sir James Paget: "Better treatment will follow better diagnosis, and better diagnosis will certainly follow a more exact pathology." Professor Thierfelder, of Rostock, says: "The predisposition to habitual hepatic congestion is often inherited, and may then appear in the same families for many generations. It must obviously be admitted that there may exist a similar predisposition towards a menstrual hyperæmia of the liver. A somewhat analogous condition is suggested also in that form of hyperæmia due to obstruction. In certain affections, for instance, it is not always the liver, but frequently the kidneys or the mucous membrane of the digestive apparatus, that constitute the organ in which the results of over-distension of the entire venous system first of all and most distinctly appear; and with reference, moreover, to the degree of the alterations in the liver, the separate cases present varieties which are by no means invariably proportionate to the extent of the obstructions to the circulation, in consequence of which, as is stated by Botkin, the susceptibility of the liver to the effects of an increased venous pressure cannot be the same in all individuals."

Biliousness, or bilious attacks—however vague the terms, and however incorrectly applied—are very frequently merely attacks of acute dyspepsia or migraine. According to Dr. F. T. Roberts, the most prominent symptoms of a supposed bilious attack are anorexia, furred tongue, a bitter taste, sickness, constipation, and headache, with a feeling of marked depression and general malaise. However such attacks may be designated, everyone knows, at least, what is meant by a bilious attack; and although the liver may have little or nothing to do with them, yet they have from the earliest history of medicine been associated with biliary derangement, and as such they are still popularly regarded. Irrespective of their causation, there can be no doubt that a predisposition to them is frequently inherited, a fact which is demonstrated unmistakably in every-day practice. So far as I know, this is the only case in which temperament may be confounded with diathesis; but as the former term does not imply any proclivity to disease, we may assume that those predisposed to bilious attacks have inherited a constitutional peculiarity which might be more aptly described as of the nature of a bilious diathesis, owing to intensification during transmission. However we may map out the differences between families or individuals, a certain amount of elasticity must be allowed, as they cannot be regarded as hard and fast lines. Thus when we employ the terms—temperament, diathesis, idiosyncrasy, etc., to designate certain classes of individuals, we must remember that no individual can be regarded as a pure unmixed type of either sub-division: no arbitrary line may be said to divide the one from the other, although heredity and variability are the two laws to which they are all subject, and from which all individual differences arise. The above terms can only be regarded as indicating in broad characters the sum of certain types of individual differentiation, and for all ordinary purposes they are explicit enough, as they are easily understood, and without embodying the whole truth, are yet verified by experience. At the same time, it must not be forgotten that every individual presents such a mingling of temperaments, diatheses, etc., that for anything beyond the broadest outlines we must seek still deeper, and further backwards into the long descent of constitutional peculiarities. Whether this bilious predispo-

sition be included under the name of temperament or of diathesis, or of both combined, the fact is, that instead of being as much a distinct type as the other diatheses, it is often rather a modification of, or co-existing with, others. Thus it is frequently associated with the gouty or strumous diatheses, and with the nervous and lymphatic temperaments, and, as Dr. Milner Fothergill says, to recognise such combination in practice, and in the selection of remedial agents, is often more practically useful than an elaborate physical diagnosis, and is especially useful when physical diagnosis is not readily attainable. Whether also the liver, stomach, spleen, pancreas, intestines, or nervous system, be primarily involved in the production of those attacks usually denominated "bilious," the fact is, that they depend, as a rule, upon constitutional peculiarities of viscus, tissue, membrane, cell, vessel, or nerve, which evidence a predisposition, not only inherited, but also transmissible. I have known cases in which these so-called bilious attacks have characterised parents and children through several generations, and the same fact has doubtless been frequently observed by others; and, curiously enough, I have seen individuals in whom the bilious temperament seemed to preponderate, but who had never experienced a bilious attack in their lives. These and similar anomalies indicate the imperfections of the most scientific grouping of the differences between man and man, but like the ideal law of heredity which is never attainable, these groupings, if necessarily imperfect, are yet satisfactory enough to merit the recognition of experience in the present light of scientific inquiry. Like all other sub-divisions of natural laws, they consist of groups of phenomena which, however imperfect or incomplete in detail, are yet sufficiently capable of indicating their dependence upon the parent law as to demonstrate its existence, and in what direction we must seek for the causes of which they are the effects.

When alluding to the temperaments, I was careful to define the term as "applicable to the sum of the physical peculiarities of an individual, exclusive of all definite tendencies to disease," as no special proclivity is involved by them, and stated that they ought to be regarded as merely physiological peculiarities forming a part of the original organisation of the individual. To the original four temperaments—viz., sanguine, nervous, bilious, and lymphatic, Dr. Laycock added two more—viz., the phlegmatic and melancholic; but of these, I agree with Mr. Hutchinson, in regarding the bilious and the melancholic as simply different degrees of the same thing, and that, as life advances, the one is very apt to pass into the other: moreover, that the distinguishing feature in both is one which concerns disease rather than temperament, and which might be more conveniently known as the *hepatic diathesis*. For, as Mr. Hutchinson continues: "It is the proneness to disordered function on the part of the liver, its ready and frequent occurrence, which for the most part stamps peculiarity on both these so-called temperaments. Further, it is much to be doubted whether this facility to hepatic disturbance would be found in association exclusively, or even generally, with any particular cast of the features, or recognisable peculiarities in the general frame." Be this as it may, it appears absolutely necessary that we should recognise a hepatic *diathesis*, the possession of which is usually characterised by oft-recurring attacks of biliousness, and that like the majority, if not all, of the diatheses, this also is hereditary. It is thus advisable to distinguish between the bilious temperament, and the bilious or hepatic diathesis—the former being a question of phy-

siology and race, if not of diathesis also; the latter signifying an easily recognised morbid proclivity, which is pathological, and unquestionably hereditary.

I have now considered the principal degenerative diseases and functional derangements of the liver, with a view to tracing the influence of heredity in each, and we have seen in the degenerative forms of disease referred to, that they each depend upon a pre-existing disposition which is constitutional, and may be transmitted from parents to children, or from one generation to another. We have also seen that the various functional disorders of the liver are subject to the same influences. In the cases of some of the diseases and derangements alluded to, the evidence may not be so strong as in those of others; but in making, so far as I know, the first attempt to show that the pathological processes, no less than the physiological and psychological processes in man are subject to heredity, and in viewing for the first time the entire field of human diseases with that object, some allowance should, I think, be made, if I have been unable to prove my argument in every case alike, especially as the entire subject is comparatively new and hitherto unworked. Here and there the evidence is positive enough; in other cases it may seem neutral, or even negative; but I feel assured that the more attention is directed to the systematic and painstaking accumulation of facts, the more will the positive and confirmatory evidence increase, and the more plainly will it be revealed that, as our bodies and minds are dependent upon heredity, so also does a predisposition to the diseases of both depend upon this great law of our being.

(To be continued.)

"ELECTRO-THERAPEUTICS."¹

By H. MONTAGUE MURRAY, M.D., M.R.C.P.,

ASSISTANT-PHYSICIAN TO CHARING CROSS HOSPITAL, AND PHYSICIAN IN CHARGE OF THE ELECTRICAL DEPARTMENT.

SYLLABUS.

GENERAL PRINCIPLES (provisional).

Action of current.

1. On *diseased* part (*a*) to allay irritation, (*b*) to improve nutrition.
2. On *paralysed* part (*a*) to preserve nutrition, (*b*) to improve nutrition in *diseased* part (reflexly).
3. On *nerve tract above diseased part* to overcome the supposed obstruction.

APPARATUS.

1. Batteries—Two kinds.

I. Galvanic, voltaic, constant or continuous.

II. Faradic, induced, or "interrupted."

Essential properties of suitable batteries.

(I and II) Constancy, accessibility, portability (weight, size, security of contents).

(I only) Galvanometer, collector, key, commutator—their uses.

(II only) Efficient graduating apparatus.

2. Rheophores—Form, length, connections.

3. Electrodes—Form, size, position.

Positive or Anode; Negative or Kathode.

APPLICATION OF CURRENT.

1. Preparation of skin—moist or dry.
2. Methods—stable, labile, interrupted, voltaic alternatives.
3. Strength of current.
4. Duration of sitting.
5. How often to be repeated.
6. When treatment should be commenced, and how long continued.

THERAPEUTICS.

1. Pain—Neuralgias.

Special forms—facial, cervico-occipital, sciatica.

2. Spasm.

Special forms—facial, trismus, torticollis, asthma.

3. Paralysis.

(1) Sensory only—generally hysterical.

(2) Motor or motor and sensory.

a. Cerebral—hemiplegia.

b. Spinal—anterior poliomyelitis, lead paralysis, paraplegia.

c. Peripheral—facial, musculo-spiral, diphtheritic.

4. Miscellaneous—Hysterical paralyses.

Aphonia.

Rheumatic joints.

5. Electrolysis—Principles.

In treatment of nævi, warts, moles, and stray hairs.

ELECTRO-THERAPEUTICS are in a transition state. Exposed to all the fallacies that beset therapeutic investigations, they are emerging but slowly from a condition of absolute empiricism. The instances are still few in which we can offer an explanation—in the least degree adequate—of the rules which determine the details of our procedure. It is something to be able to speak with certainty about details, but it would be infinitely more to be able to formulate principles from which those details would be necessary deductions. I have said this much, lest you should think that the provisional principles I have put down at the beginning of the syllabus, are universally accepted inductions. They are not. They are simply the ordinary methods of procedure expressed in general terms. I have adopted them merely as working theories, to be cast aside as soon as better ones can be found. Nevertheless they will, I think, prove useful if only for illustrative purposes.

If you will refer to them, you will find that *three* regions are mentioned as possible points for the application of electric currents: (1) that part, generally of the nervous system, which is itself diseased; (2) those parts whose functions are affected in consequence of such disease; and (3) that part of the nervous tract immediately above—that is, just central to—the lesion.

Still further: you will find it stated that currents may be applied directly to diseased parts for one of two objects: (1) to diminish irritability, whether in the form of spasm, or of pain; and (2) to improve the condition of nutrition, such for instance as in hemiplegia and paraplegia. The distinction between these two actions is mainly clinical. It is quite possible that we diminish irritability by improving the nutrition, and that in improving nutrition we allay irritability. But into these questions we cannot now enter. Again: you will find under the second heading that currents are applied to paralysed parts themselves, in order to preserve their nutrition; for example, the local galvanisation of muscles in hemiplegia or in infantile paralysis. This is the use of electricity with which probably you are most familiar. Once more: a lesion in a nerve trunk has been compared to a plug in a water pipe, and it has been suggested, that just as increased pressure may force the plug out of the pipe, so increased stimulation of the upper healthy portion of the nerve may do something to overcome the resistance in, and thus enable the impulse to be transmitted through, the previously diseased portion. Very frequently this method is unavailable; the lesion being too high up—so high, that the still higher healthy part is inaccessible. The difficulty is to some extent met by reflex action. By stimulating the efferent nerves of a limb, we hope to overcome the obstruction situated high up on the

¹ A lecture delivered at the Charing Cross Hospital, in the Post-Graduate Course, 1887—1888.

effluent tract. This then furnishes us with a second reason for the local application of electricity to paralysed parts; and if it does not explain, it at any rate helps us to remember, that sometimes one form of current, and sometimes another, is most beneficial in paralyses due to central causes.

To put the facts in another form—we have four possible objects. *One* is to preserve the local nutrition of the paralysed parts; while the other *three* are efforts to attack the diseased area: (1) by acting directly upon it; (2) by directly stimulating the part above it, and thus trying to force a passage through; and (3) by reflex action to produce the same result when we are unable to apply the current directly.

We will now pass to a consideration of the apparatus needed for electro-therapeutics. I cannot in the time allotted me go fully into the construction of batteries. I propose to confine myself to some few practical considerations that may aid you in estimating the merits of different batteries. Two kinds of battery are needed. These may be supplied in a single box or in separate boxes. In this matter you have only to consult your own personal convenience. The two kinds are known by the various names printed on the syllabus. I have nothing to add to these, except the remark, that the commonly used term "interrupted" is inadmissible, as it is often used in quite a different, and quite a legitimate, sense. I put it down here merely to warn you against the confusion that may arise from its use.

All batteries should be constant in their action, readily accessible, and portable. By portability I mean light weight, small size, and the construction such that the contents will not easily be spilt. Unfortunately it so happens that the more portable a battery, the less constant, and the less accessible are its parts. If you require a battery for use at your own house only, portability becomes a consideration of less importance; so get one with large cells, and with the parts readily accessible. If, on the other hand, it is to travel, get one as large as you can conveniently take charge of yourself. While it is on its journey never lose sight of it. It is better to err on the side of having a battery too large rather than too small; and when one does not happen to live in an atmosphere of instrument-makers, it is a great advantage to be able to find out the exact nature of a defect, and possibly to be able to remedy it. It is one of the disadvantages of small batteries that this is impracticable. Shape is of some moment. Batteries contained in *oblong* boxes are more portable than those in *square* boxes. Supposing, for example, that you need an ordinary faradic battery, worked by one, two, or three cells, and a voltaic battery, with forty cells; the most portable arrangement would be to have two oblong boxes, one containing the faradic battery, and about fifteen cells of the voltaic, the other the remaining twenty-five cells.

Now beside the size, shape, and mechanical attributes of batteries, comes the question which is the best kind of cell. The choice lies between two types. There is the *Leclanché* cell, or one of its many modifications, on the one hand; and the *Stohrer*, or some form of sulphuric acid cell, on the other. My own preference is altogether for the former. They certainly require much less attention, and the contents are not likely to be spilt. In the case of the acid batteries, on the other hand, frequent changing of the fluid is necessary; and this, when travelling, must be carried separately, and added to the battery at the

journey's end. Nor even thus is sulphuric acid a pleasant travelling companion. It is only fair to add that modern manufacturers have made the cells so long and narrow, that the chance of spilling the fluid is reduced to a minimum. Against the *Leclanché* it may certainly be urged that it is easy to do serious damage if the printed directions concerning its use be disobeyed: this leads me to say that directions clearly stated, distinctly printed, and firmly affixed to the inside of the lid of the box, should be issued with each battery. To sum up: large *Leclanché* cells best ensure constancy. Accessibility you can judge of yourself, but never get a battery without clearly comprehending the connections and uses of the different parts. To ensure portability, get oblong shaped batteries, and *Leclanché* cells, limiting the size only by the weight you are prepared to put up with. If you must give up anything, give up the accessibility; and if the battery is for *home use*, and you do not mind extra trouble so much as extra expense, you can get acid cells, for they are cheaper. And here I must leave the matter.¹

We have now to discuss the essential accessories of galvanic batteries:

Firstly, the battery must be provided with some piece of apparatus by which you can measure the exact dose of electricity you administer. It is absolutely and utterly useless to talk about using six cells or twenty cells. You may get with six cells, under some circumstances, a stronger current, than with twenty under others. You might as well tell your patient to take, three times a day, as much medicine as he could drink in a minute. One patient would take a drachm, another a pint. The number of cells employed only tells us the force we are bringing to bear; the strength of the current, which is really passing, will depend, not only on the initial effort, but as much upon the resistance encountered. We require, therefore, an accurate measure of the actual current passing, and this is provided by a *galvanometer*. A galvanometer is employed by everyone in diagnosis, but is still omitted in most batteries intended for therapeutical purposes. It is, in electro-therapeutics, what weights and scales and measures are to ordinary prescriptions. The electrical unit is now universal, and that fraction of it which has become the *medical unit*, is just as universal; so that all medical galvanometers are graduated according to the same scale. This unit is known as a milliampere. The position of rest which the indicator of the galvanometer assumes, while the current is passing, shows its strength in milliamperes at any given time. For ordinary purposes a range of from one to twenty milliamperes is sufficient. But if it is to do duty for *electrolysis* as well, it must measure up to 200 or 300. When the battery is bought by the patient, and the cost of the galvanometer considered to be too great, that piece of apparatus may generally be hired.

The second accessory is a *collector*. Supposing you wish to pass a current of five milliamperes through a definite part, you cannot exactly foretell how many cells will suffice. It is, therefore, advisable that you should have a ready means of altering the number of cells in action. The instrument consists of a dial and a movable indicator, the position of the latter showing the number of cells in action. This is a great convenience, but not an absolute

¹ Sulphate of mercury batteries have a good reputation. They are more portable than acid batteries, and the cells are more easily recharged than the *Leclanché* elements. I have not had any personal experience of them.

necessity. The same result can be obtained by changing the position of the connecting wires. But collectors are not expensive. They save time, and should certainly be provided in a battery intended for your own use. In a patient's battery, where time is of far less importance than expense, they may be omitted.

A *key* is an instrument for suddenly starting, or suddenly discontinuing the current. The object of a *commutator* is to rapidly reverse the poles; that is, to make the positive pole negative, and the negative positive. The two are generally combined in one piece of apparatus. Both key and commutator are essential in a battery intended for diagnostic purposes, and a great advantage in those intended only for treatment. To sum up: every battery should be provided with a galvanometer; this is essential. Collectors, keys, and commutators are extremely useful accessories; but are not absolutely essential unless the battery is intended for diagnosis or for your own personal use.

Into the general construction of faradic batteries there is no time to enter. Nor is this a matter for great regret, as you are not likely to go far wrong in your choice of one. In their construction sulphuric acid cells, of the Stohrer type, are generally used. I think this is a mistake. I have tried both, and prefer the Leclanché elements. You will have to decide between two kinds of coil: one in which the distance between the primary and the secondary coils can be altered at will, and the strength of the secondary current, which varies with the distance, thereby regulated; in the other the secondary coil is wound directly over the primary, the strength of the latter being regulated by a central pin, and that of both primary and secondary by the intervention of a *rheostat*. This instrument introduces into the current an amount of resistance, which can be definitely regulated, and the current accordingly proportionately diminished. The arrangement in which the two coils are separate—that is the first—is probable the better.

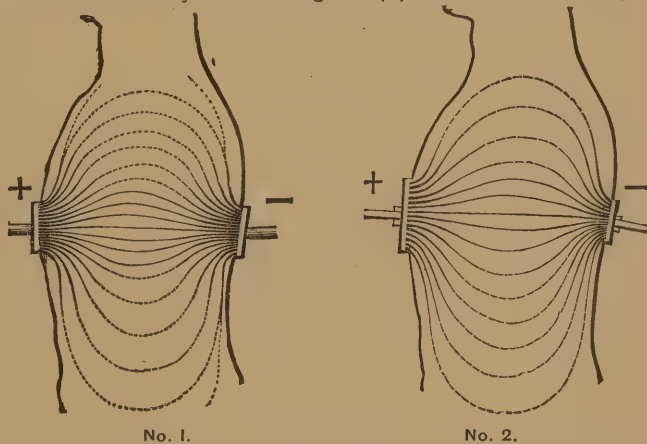

The conducting wires which convey the current from the battery to the body are technically known as *rheophores*. Each should be made of a number of fine wires, enclosed in a small india-rubber tube, or otherwise effectually insulated. Each cord should be one and a half or two yards long. The ends of the wires should be both soldered and tied to rigid metal terminations. If only tied, they become loose, and the current is consequently interrupted. If soldered without supports, they become brittle, and break at the point of soldering. There are various mechanisms by which these two difficulties may be avoided.

Electrodes are the instruments by which we apply the current to the body. When it is to be applied through the skin, they consist of plates of metal or of carbon covered, according to fancy, with a thin layer of fine sponge, or with three or four layers of coarse flannel, or with amadou; over this a thin cover—linen, thin flannel, or wash leather is slipped. The cover should be easily removed, easily washed, and easily replaced. The smaller electrodes are disc shaped, and can be screwed to an insulated handle; the larger are oblong or elliptical, and fitted, sometimes with a handle, and sometimes only with a binding screw. The larger electrodes should invariably be made of such metal as tin or lead, so that they can be accurately shaped to the part to which it is intended to apply the current. For general purposes, four are requisite. One which is called *small* should be $\frac{3}{4}$ in. in diameter; the second or *medium* electrode, $1\frac{1}{2}$ —2 in.; the third, called

large, about 2 in. by 4 in.; and then lastly, and this chiefly for applications to the head, one about 3 in. by 6 in., or *very large* electrode. If any still larger are needed, as in Apostoli's method, a layer of modelling clay is interposed between the metal electrode and the skin.

For internal application special electrodes are required. The principles running through them all are: that the instrument is shaped to reach the point of application, and that it is insulated almost up to the end to prevent the current from escaping before it reaches the extremity. The electrode known as the *faradic brush* is, in its best forms, not unlike a miniature hair brush, in which, for many of the bristles, are substituted pieces of fine wire. All metal work in electrodes should be thickly plated, as brass rapidly corrodes. It is difficult to give clear rules which shall form efficient guides to the size of the electrodes to be used. If in doubt between two, use the larger, especially when deeply placed parts are concerned. The larger the electrode, the less the resistance, and the stronger therefore the current. But the larger the electrode, the more diffused the current, so that the degree of concentration required is really our limit of size. More explicit directions will be given when we come to the special diseases.

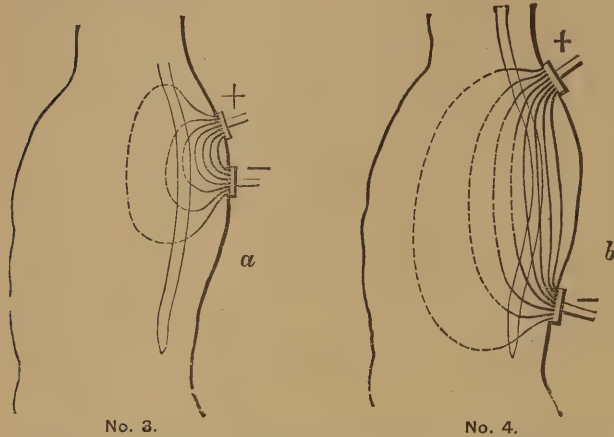

The position of the electrodes depends on considerations I can best illustrate by means of diagrams. In (1) the electrodes, equal in size, are represented on opposite sides of the body, and the current is supposed to diffuse itself after the fashion shown by the shading. In (2) one electrode is large,

by which means a stronger current enters the body than in (1), and a greater concentration is obtained at the smaller electrode. In (3) and (4) the effects of placing the electrodes near together, or far apart, are shown. From them it will be seen that when the spinal cord, or any part, an inch or more beneath the surface of the skin, is the object of treatment, the electrodes must not be placed too near together. The electrode attached to the positive pole of a battery, is called the positive electrode or anode; that attached to the negative, the negative electrode or cathode. Generally speaking, the action of the positive electrode is soothing, and that of the negative stimulating. The chemical changes at the negative pole are so marked, that unless the electrode be large, its continued application to any one part is likely to produce local inflammation. Apply your electrodes firmly. Nothing is more irritating to the patient than the frequent interruptions of the current due to hesitating manipulation.¹

¹ Erb Electro-therapeutics Translated by Dr. de Watteville.

In describing to you the exact procedure adopted in the treatment of the various diseases, it will be necessary for me to discuss with you, not only the kind of battery, and the size and position of the electrodes to be used, but also to enter into certain other details, briefly stated in the syllabus under the heading of "Application of Current."

No. 3.

No. 4.

The skin offers an enormous resistance to the passage of the electric current. The drier the skin, the greater the resistance. The moister the skin, the less the resistance; hence the rule that the skin over which it is intended to apply the electrodes must be thoroughly moistened. And, as hot water is a better conductor than cold, and as it more effectually moistens the skin, hot water should be used. Once more: acidulated water is a better conductor than ordinary water, so that it is well to add a little acetic acid before using it. To recapitulate, well moisten the skin with hot acidulated water. Formerly salt and water were used, but salt corrodes, and forms incrustations on the electrodes; on the whole, it is more nuisance than it is worth. A small sponge may be used with advantage to effect a preliminary moistening before the electrodes are applied. Due precautions must be taken to prevent wetting the clothes. There is one exception to the foregoing rule. It is this. When the faradic brush is to be used the skin must be dry, and not only dry, but very dry. The current is, in this case, intended to stimulate, especially the ends of the sensory nerves. With this object in view, the skin is first wiped dry with a towel, and then freely powdered with ordinary toilet or starch powder. This is the only exception. In all other cases moistened electrodes are applied to the moistened skin.

There are four methods of applying the current. In the *stable* method the electrodes are first placed in position; a weak current is then passed, insufficient to cause the least sensation, the position of the electrodes being all the time maintained. Gradually the current is increased until the required strength is reached. This is maintained for the desired time. Then, as gradually as before, the strength of the current is diminished, until finally it is shut off altogether. The electrodes are then removed, and the process is at an end. In this way, with large electrodes, very strong currents may be borne with no sensation worse than a little tingling; whereas the *sudden* application or cessation of the same current might be absolutely dangerous to life.

The second is the *labile* method. This bears the same relation to the *stable*, as the temperature in remittent does

to that in continuous fever. The electrodes, as in the former method, are first placed in position, and the current similarly raised to the desired strength. Then one of them, usually the negative, is moved to and fro over the part you may wish to influence. The electrode is never raised from the skin, and the current, therefore, is never broken; but, as may be seen by watching the oscillations of the galvanometer, its strength varies within distinct but moderate limits. Its main action seems to depend upon the fact that successive portions of the subjacent parts are thus brought rapidly under the action of the current, as the electrode passes over them. Without producing violent shocks, the general effect is stimulating.

In the *interrupted* method the current is actually broken. As before, one electrode is fixed, and the other—again the negative—is *painted* over the affected part. This method is more stimulating than the preceding. If used about the head or neck, it must be employed with great care.

Lastly, the most stimulating process of all is to place the electrodes, turn on the current, and then, by means of regular movements of the commutator, to rapidly reverse the poles—making each alternately positive or negative.

The strength of the current to be employed depends so much upon the special features of the case that it is difficult to formulate any rules having much practical value. Stronger currents may be used with the *stable* method than with any other. When applied to the head the current should always be weak—not more than from three to five milliamperes. On the other hand it may be necessary, when dealing with peripheral nerves such as the sciatic, to employ a current-strength of from twenty to thirty milliamperes, though ten to fifteen are generally sufficient. In electrolysis still stronger currents are used.

The whole "sitting" should rarely exceed a quarter of an hour; and the current should not be applied to any one part for more than from two to five minutes. When applied for its sedative effects two or even three sittings a day may be necessary. In the majority of cases an application every day, or every other day, is sufficient.

In vascular and acute inflammatory lesions of the brain and spinal cord electrical treatment should not be commenced until a month after the onset of the disease. In other cases the treatment may date from the time the patient comes under our care. How long the treatment should be continued is a question to which the answer is dependent on the nature of the disease and the results of the treatment.

I have put *neuralgia* first in the list of diseases benefited by electricity, because, in my experience, there is no condition in which its immediate achievements are more marked. What I have to say concerning the treatment of both pain and spasm, refers only to those varieties for which no removable cause can be made out; such, for instance, as diseased teeth or local pressure. To return to neuralgia, the general method of procedure is as follows:—use the continuous current and the *stable* method of applying it. Search carefully for tender spots. Place the positive pole over, or a little centrally to them, and the negative pole a few inches nearer the periphery. The exact distance between the electrodes depends on the depth of the nerve from the skin, according to the principle illustrated by diagrams 3 and 4.

The electrodes should be large, whatever current is used, and *very* large if the stronger currents are required; four to six milliamperes are often sufficient to cause relief, but not infrequently ten, fifteen, or even twenty, may be needed.

The current is maintained for four, six, or eight minutes, and then gradually shut off. Relief should occur at the time. The process should be repeated once or twice during the day, especially if, after temporary relief, the pain return. Half a dozen applications will, in many cases, effect a practical cure. If this plan fail, apply the positive electrode to the most peripheral of the tender spots, and the negative to the point nearest the origin of the nerve. Subsequently apply the positive to the other tender spots. Occasionally, faradism, employed in a precisely similar manner, will succeed where galvanism has failed. Still more rarely the faradic brush, attached to the negative pole, while the positive is placed over a central part (moistened) will be successful.

As regards the special forms of neuralgia—if the *fifth* is affected, place the positive pole over the exit of the painful branches, and the negative at the nape of the neck. The infra-orbital is the branch least amenable to treatment. *Cervico-occipital*, or neuralgia at the back of the neck, is best treated by placing the positive pole at the points of exit, and the negative on the vertex; or, failing this, on the sternum. No current applied to the head should exceed five milliamperes, and two or three are often sufficient. *Sciatica* often presents very encouraging results. Apply the positive electrode over the sacro-sciatic notch, and the negative six inches lower down. Gradually move the electrodes down the course of the nerve, maintaining the distance between them. Use very large electrodes, and strong currents—twenty milliamperes, or more if necessary. Let the whole sitting last ten minutes.

The treatment of *spasm* is much less satisfactory than that of neuralgia, and generally fails. Occasionally, as in this disease, tender spots may be found along the course of the nerves supplying the affected muscles. If you find any, deal with the case exactly as if it were one of neuralgia. If you do not, and if, as in many cases, you are unable to determine whether the causative lesion is central or peripheral, you must deal both with the centre and periphery. For the centre use the continuous current, the stabile method, a strength of four milliamperes, and pass the current for five to seven minutes. Apply the treatment daily. Very large electrodes should be used, the positive over the centre, and the negative at the nape of the neck. The treatment of the periphery is less definite than that of the centre. Sometimes a sedative treatment, like that employed for neuralgias, is most effective; sometimes a stimulating one, as strong faradism or voltaic alternatives. In all cases the electrodes must be applied along the course of the nerve as before described. If all these fail, the faradic stimulation of some distant part is said to be occasionally beneficial. As regards the special forms—in *facial* spasm, turn your attention principally to the centre; in *torticollis* and in *trismus*, to the peripheral nerves. In *torticollis*—or wry neck, as it is generally called—faradism of the muscles of the opposite side is, for some occult reason, occasionally of great service, but many cases resist all treatment.

Electricity is occasionally of use in *asthma*. It is employed with a view of cutting short the paroxysm, and in lengthening the intervening periods. Of this I have had no personal experience, but the condition is one which taxes our therapeutical resources so severely, that we gladly welcome any possible remedy. It is recommended in those cases in which no source of peripheral irritation can be discovered. The plan which seems to be most frequently

successful is the galvano-faradisation of De Watteville, or in other words, the simultaneous passage of the galvanic and faradic currents. Failing this, use the faradic current alone. Place the electrodes several inches apart in the interval between the nape of the neck and clavicle, as experience may determine. This is to cut short the attacks. During the intervals, regular stabile galvanisation of the vagus from the nape of the neck to the epigastrium seems to be the most satisfactory treatment.

We have now to deal with that large class of cases grouped under the term paralysis. Paralysis which is wholly sensory is often hysterical. When this is the case it should be treated by the faradic brush. The skin must be dry and powdered. The secondary coil of the battery should be used. A moist electrode is attached to the positive pole, and applied to some indifferent point, such as the sternum. A current which just stops short of producing pain should be employed. Occasionally an uninterrupted voltaic current, with frequent reversals of the poles, will prove even more satisfactory. The prognosis in these cases is good.

In *hemiplegia*, no electrical treatment should be commenced until a clear month after the onset of the paralysis. In all cases in which late rigidity has not set in, it may be tried; but it is only in those of a few months' standing that much benefit is likely to ensue. If no improvement occur after two months' treatment, it need not be continued. The parts to be brought under the influence of the current are (1) the diseased centre and (2) the paralysed limbs. Commence with the continuous current. Connect a large electrode with the positive pole, and fix it at the nape of the neck.¹ The negative pole is then placed on *three* different parts successively. (1) By means of a very large electrode apply it to the head, so that the diseased area shall lie in the tract between the two electrodes. The method must be strictly stabile, the strength three or four milliamperes, and the duration two to three minutes. (2) Transfer the negative electrode to just below the ear with the same precautions, but with a current strength of four to six milliamperes, moving it, at the end of three minutes, to the similar place on the opposite side, for the same time. (3) Lastly, the negative pole should be applied by means of a medium electrode to the paralysed limbs, which should be rubbed with it, somewhat vigorously, according to the labile method. About four minutes is spent over each limb. The current employed is still stronger, generally about ten milliamperes. The whole sitting thus lasts rather more than fifteen minutes. It should be repeated once every day, or every other day. The only exception to this procedure is that the primary current of the faradic battery may occasionally be substituted for galvanism when dealing with the paralysed limbs themselves.

In spinal diseases the guiding principles are similar. Under the term "*anterior poliomyelitis*" I include all conditions, whether in children or in adults, depending upon acute or sub-acute inflammation of the anterior cornua. As in hemiplegia commence treatment a month after the onset. First treat the diseased area of the cord by covering it with a very large positive electrode, placing the negative on the front of the body. Use a current strength of five to ten milliamperes, and pass the current for three or four minutes, according to the stabile method. Then remove the nega-

¹ This method of procedure is advocated by De Watteville. It is certainly more successful than the common plan of merely treating the extremities.

tive electrode, and with one of a medium size, substituted for it, rub the paralysed parts of the limbs. The current should be strong enough to contract the affected muscles, but not strong enough to contract their opponents. This is a point often neglected. Ten or fifteen milliamperes are generally needed, and five minutes should be devoted to each affected limb. When dealing with children, use no current at all during the first sitting. This is in order to accustom them to the machinery. It is worth a great effort to be able to galvanise a child regularly without your treatment being the daily terror of its life—as it too often is.

Lead poisoning need not detain us. Whatever be its pathology, treat it as if it were an affection of the anterior cornua; that is, exactly like the preceding class.

Paraplegia, when due to inflammatory conditions, is very generally benefited by electricity. As in the two previous groups, do not commence your treatment for a month, and use the galvanic current. Again, as in hemiplegia, apply the positive electrode to the nape of the neck, and the negative on *three* places in succession; first of all just above the lesion; secondly, just below it; and thirdly, to the lower limbs. The current in the first case should be from five to eight milliamperes, in the second from ten to twenty, and in the third, where a smaller electrode is used, about ten, or just sufficient to produce muscular contractions. Two minutes are occupied with the first, two with the second, and two or three for each limb. In the first and second the stabile method is used, and in the third the labile. Repeat the sitting every other day. Special attention has often to be paid to the bladder and rectum. The easiest method is to place large electrodes over the sacrum and hypogastrium respectively, or over the hypogastrium and perinæum, and then to reverse the poles every second for about two minutes; or else to employ faradism in the same fashion. There are other methods involving the introduction of electrodes into these viscera, but into the precautions essential to their success I have now no time to enter.

Peripheral paralyses are so numerous that I can only refer to a few of them. If we can get at that part of the healthy nerve situate immediately above the diseased portion, the treatment is simple enough, and is analogous to that employed in both cerebral and spinal cases. The positive electrode, varying in size according to the nerve, is placed just above the diseased area, while the negative is applied (1) just below it according to the stabile method; and then (2) to the peripheral distribution of the nerve, according to the labile method. In *facial paralysis* we are rarely able to get behind the disease. Empirically we place a positive electrode behind the ear, and, with the negative, sponge according to the labile method the various muscles it supplies. Every muscle should be individually treated, and if possible, made to contract. The current strength needed may be as little as two milliamperes. Sometimes a current of six to eight milliamperes is requisite, but in many cases it cannot be borne. It is quite possible that this treatment acts reflexly, and this is still more probable in those cases where the faradic current has been substituted for the galvanic, and improvement resulted. An application every other day for five minutes generally suffices.

In *diphtheritic paralysis*, if either legs or arms be paralysed, they should be treated according to the rules laid down for poliomyelitis. Recovery of the soft palate may be accelerated by electricity. Use a galvanic current; apply the

positive pole to the nape of the neck, and the negative, by means of a suitable electrode to the soft palate, while the patient is taking a deep breath. From the nature of things the *interrupted* is the only method that can be employed. Three to four milliamperes are quite sufficient, and, as the resistance in mucous membranes is less than that of the skin, very few cells will produce the desired strength.

About *hysteria* I have little to say. Treat the disease according to its presumed locality, whether it be due to functional or organic causes. There is this difference: if the condition is functional, galvanism is more likely to fail and faradism to succeed.

Aphonia if hysterical, may often be cured or relieved by the passage of a current transversely through the larynx. Use the galvanic current according to the interrupted and reversing methods. Place medium sized electrodes on each side, and pass, for three or four minutes, currents not exceeding five milliamperes. If this fail, try faradism; do not, as a rule, attempt intra-laryngeal treatment.

The pain of chronic rheumatism is occasionally relieved by the passage and reversals of currents transversely through the affected joints; but only in those cases where not more than one or two joints are implicated.

In the few minutes left at our disposal we will consider a few of the more surgical applications of the electric current. For these the galvanic current alone is used. To the galvanic cautery I have no time to allude. The procedures to which I refer are founded upon what is known as electrolysis, that is, on the chemical and, therefore, structural decomposition, which goes on so long as the current is passing; but only in any marked degree when the electrodes are metallic and small, or the current powerful. For this purpose the electrodes take the form of needles. If they are made of gold, or of platinum, they are unaffected by the decomposition occurring in this neighbourhood, and therefore remain clear and bright throughout the operation, but are often too flexible to pierce the skin easily. If made of steel the positive needle becomes eroded from the action of the oxygen and chlorine, and adheres to the tissues. Its forcible withdrawal frequently produces hæmorrhage; but at the same time it forms a firmer clot. The tendency to hæmorrhage can be prevented by reversing the current for a few seconds before the needle is withdrawn. With small nævi it is better to insert only one pole. This you may do by means of one, two, or even more needles. If the nævus is quite superficial, or if you are dealing with port wine marks, you should use the negative pole, as the destruction of tissue is essential to success, and the negative pole does this more thoroughly. If, however, the nævus is other than the smallest, and particularly if any part of it be subcutaneous, it is safer to confine yourself to the positive. If you wish to avoid the destruction of the skin you perforate, your needles must be carefully insulated to within a fraction of an inch from the point, or local sloughing of the skin is liable to occur. The danger is much greater in the case of the negative pole, especially as even the insulating material is frequently dissolved off it by the action of the current. Always use fine needles.

From these diffuse recommendations you will gather that you may have one of two objects in view: (1) To produce firm clothing in the vessels with subsequent obliteration of them; and (2) to destroy superficial areas of the skin which

shall be replaced by a thin unnoticed scar, producing less disfigurement than the original condition. In the first case the needle is attached to the positive, in the second to the negative pole. The pole which is not inserted should be placed by means of a very large electrode over the moistened skin in the neighbourhood of the nævus. Electrodes for this purpose should consist of a flexible band which may be made almost to surround the nævus. Occasionally in large nævi both poles are inserted. When this method is adopted, two, three, or four needles are attached to each pole. The needles are arranged alternately and parallel to each other, so that a negative needle is situated between two positive and *vice-versâ*. Great care must be taken lest they should touch one another inside the nævus, as in that case all action would be arrested. The strength needed varies from five milliamperes upwards for each needle.

The test for the completion of the operation is, in the case of the subcutaneous nævi, hardness of the mass. As soon as this condition is reached the current should be reversed for a few seconds, then gradually shut off, and the needle withdrawn. The strength of the current must be reduced before it is reversed in order to avoid any sudden shock. When your object is the destruction of the skin you can judge easily enough when to stop by the change in colour. A coat of collodion should be applied after the needle is withdrawn. Do not select facial nævi for your first experiments. Through small errors, or accidents, or lack of experience, you may manage to finish with a contracted cicatrix, which, occurring on the covered parts, would be of little importance, but on the skin of the face might lead to a deformity greater than that you endeavoured to remove. Warts and moles may be easily destroyed by the action of the negative pole. They are replaced by small scars—often so small as to escape notice.

The easiest application of electrolysis is for the removal of large stray hairs from the bodies of those persons who may regard them as disfigurements. Each hair must be treated separately. Place a large moistened positive electrode on the skin, a few inches from the hair, then pass the needle, attached to the negative pole, carefully alongside of the hair right down to the bulb, gently holding the hair with a pair of forceps, in order the more clearly to show the track along which the needle is to be passed. On no account should the hair be forcibly withdrawn. Then turn on the current, using one to three milliamperes. In a few seconds you will find that the hair is loose, and that it simply requires to be lifted from its place. The bulb is destroyed—the hair cannot return—no scarring results. This method is of doubtful service in those cases where the hair is abundant or fine, or when it has appeared after puberty, as it seems occasionally to stimulate the growth of neighbouring hair-bulbs.

To return for a moment to the general subject we are discussing this afternoon, I would strongly advise you, whenever it may be possible, to superintend the electrical treatment yourself. When this is out of the question, and it often is, do not rest satisfied when you have given explicit directions to the patient's friends. In the first place, write them down, and in the second, be present on at least one occasion while the treatment is being carried out. A distinguished physician recommended galvanism in a case of peripheral facial paralysis. He gave what most of us would consider to be explicit directions for the use of the battery, which was brought to, and approved of, by him; and yet for two

years the friends patiently galvanised the wrong side of the face.

Here I must conclude. My object has been to lay before you the methods adopted by those who have worked most thoroughly at the subject. Simple, though numerous, as the directions I have given you may be, it yet remains true, as well in the medical as in the surgical parts of electrotherapeutics, that experience alone can give you that knowledge which is essential to success. It is so in the use of drugs and of dietaries. It is so in all surgery. If, therefore, your first attempts have not been so successful as I may have led you to suppose they should have been, remember that it may not be wholly the fault of the agent you have employed. Electricity is no universal specific. Often it fails where we should most expect it to succeed. I believe that you will find it a useful member of your therapeutic measures; of less use than some, but of more use than many of the numerous constituents of that heterogeneous assemblage.

ON THE TREATMENT OF OBSTRUCTIVE DYSMENORRHOEA AND STERILITY.¹

By THOS. MORE MADDEN, M.D., F.R.C.S.E.,

OBSTETRIC PHYSICIAN, MATER MISERICORDIÆ HOSPITAL, DUBLIN; PRESIDENT-ELECT, OBSTETRIC SECTION, BRITISH MEDICAL ASSOCIATION; EX-PRESIDENT, OBSTETRIC SECTION, ACADEMY OF MEDICINE IN IRELAND; FORMERLY VICE-PRESIDENT, BRITISH GYNÆCOLOGICAL SOCIETY; AND EXAMINER IN OBSTETRICS AND GYNÆCOLOGY, QUEEN'S UNIVERSITY, ETC.

THE treatment of sterility and obstructive dysmenorrhœa are closely interwoven questions of great practical interest, which, up to the present time have not been referred to in the *Transactions* of the Royal Academy of Medicine. Hence, although I have elsewhere considered certain aspects of these subjects, I now venture to submit my views thereon, some of which I believe will be found novel to this Academy, in the hope of inducing a discussion on one of the most frequent, and oftentimes the most difficult, of the daily-recurring problems that come under gynæcological attention.

In so doing I would premise that it appears to me in the recognition of obstruction, from either cervical or fallopian stenosis, as the chief cause of sterility, as well as of dysmenorrhœa, will be found the key to the pathology and successful treatment of the great majority of cases of both these morbid conditions. These, as already observed, being intimately connected in their pathology and treatment, must be here dealt with in conjunction, although with special reference to the former. The frequency of such cases is much greater than is generally admitted, as in my hospital practice, during the past eleven years, upwards of eight hundred instances of obstructive dysmenorrhœa, or of sterility, similarly caused, have come under observation in a total of seven thousand gynæcological cases that have been there noted in our intern and extern departments. Nor is the pathological importance of these complaints less striking than their frequency. Thus, of all the ailments of female existence, few give rise to greater and more persistent suffering, or produce more disastrous effects, not only on the general physical health, but also on the cerebro-nervous system, and on the moral constitution of the patient, than result from well-marked obstructive dysmenorrhœa. The importance of the last-mentioned consequence of dysmenorrhœa, to which I directed special

¹ Read before the Royal Academy of Medicine of Ireland,

attention in an article of mine on the "Disorders of the Female Sexual Functions," in *Quain's Dictionary of Medicine*, is by no means as generally recognised as it should be. This is more especially evident in many cases of alcoholism, and I may repeat that a morbid craving for alcohol in women may very frequently be dated from their first painful menstrual period, when stimulants are too often forced by foolish mothers into the generally reluctant lips of their daughters. Once, however, the pain of dysmenorrhœa has been thus relieved, the girl at the next epoch of suffering naturally, and not unwillingly, seeks similar solace, until finally the victim of dysmenorrhœal alcoholism becomes an habitual, and, perhaps, an incurable drunkard.

Importance of the Study of Sterility.—The effects of the second of the morbid conditions that form the subject of this communication are certainly of no less moment in a practical aspect than are those results to which I have just referred, as consequent on the first-named ailment—the latter involving not only the physical health and well-being of our patients, but also, in too many instances, intimately affecting their social interests, and the happiness of conjugal life. In this country at least, the infamous doctrines of the modern votaries of "*Venus sine Lucilla*" have, fortunately, to no appreciable extent displaced the Christian view of the main function and chief end of woman's married life. Hence, in Ireland to the present time, as in Israel in the days of Sarah, to be childless is commonly regarded as a reproach to a married woman, and as a subject of marital disappointment and trouble.

Causes of Barrenness.—As in every other morbid condition, so in the treatment of sterility—our first aim must be to ascertain, and our second to remove, if it be removable, the cause of the trouble for which we are consulted. Of the various causes of barrenness, some—as, for instance, the absence or arrested development of the organs essential for conception—viz., the uterus, fallopian tubes, or ovaria, being beyond remedial reach, need not here occupy our consideration. In the great majority of instances, however, sterility, occurring in women within the limits of ovarian functional vitality, admits of effectual treatment, when that treatment is rationally directed to the special exigencies of each case.

By most authorities on the subject, including even the late Dr. Marion Sims, female sterility, or reproductive inability, has been confounded with impotency, or sexual incapacity. Hence, it may not appear superfluous to remind my hearers that, properly speaking, the latter term should be restricted to those cases in which marital intercourse is prevented by some physical impediment or malformation in the female genital tract—such as vaginal or vulval occlusion, imperforate hymen, vaginismus, cervical stenosis, etc., by which impregnation may be precluded, whilst sterility or imperfection of conceptive power is due to either some structural lesion, deficiency, displacement, or flexion of some one of the organs essential to conception. Thus, the uterus, fallopian tubes, or ovaria, may each be absent, misplaced, or otherwise abnormal, or else these parts, being in a normal condition, the patient nevertheless remains sterile, either from constitutional causes or from other causes—such as sexual irrespondence or incongruity, of a moral rather than of a physical nature.

Stenosis of the Cervical Canal.—This, according to my experience—now extending over a quarter of a century, in hospital and in private consultation, at home and abroad—is not only the most frequent of all the causes of sterility,

but is, moreover, the most amenable to appropriate treatment of all the physical factors in the causation of infecundity. Until a recent period, however, neither the frequency nor the rational treatment of this cause of barrenness were recognised by modern surgeons, although both were clearly pointed out by some of the older writers. Thus, it was not until the late Sir James Simpson recalled attention to the plan of dilating the os uteri and cervical canal by a method which, several years previously, had been suggested by another Edinburgh surgeon—whose ignored suggestion on the use of sponge tents in the treatment of dysmenorrhœa Simpson revived—that anything like adequate attention was drawn to this important subject. But both Simpson and Mackintosh were forestalled in their views by ancient writers, whose names had long been forgotten, and whose works had apparently become hermetically sealed by the hand of time. Hence, as I believe that the history of the steps by which modern gynæcological science has arrived at its present development are well worthy of the consideration of all who pride themselves on being members of a learned and liberal profession, I venture, in this connection, to recapitulate, briefly, a few observations which I made several years since, before a society which no longer exists, on this point.

The credit of suggesting the dilatation of the os uteri and cervical canal by means of sponge tents is, as already said, generally conceded to the late Sir James Simpson, by whom it was claimed, in a paper of his published in the *Edinburgh Journal of Medical Science* for January, 1850, in which he says: "In 1844, in a communication laid before the Medico-Chirurgical Society of Edinburgh, I proposed a means of safely opening up the cavity of the cervix and body of the uterus to such an extent as might enable us to introduce a finger into the uterine cavity for the purpose of diagnosis in the treatment of this (uterine polypi) and other morbid conditions of the organ. The means described consisted in the introduction of sponge tents into the os and cavity of the uterus, so as gradually to dilate these parts to the degree required." This suggestion was then looked on as "marking the commencement of a new era in uterine surgery." It is, therefore, not a little interesting to find that a similar method of dilating the os uteri was well known and described some two centuries and a half ago. Thus, in "The Method of Physic, containing the Causes, Signs, and Cures of Inward Diseases in Man's Body from the Head to the Foot," by Philip Barrough, and "most humbly dedicated by the author to his singular good lord and master, Lord Burghley," the eighth edition of which was published in 1639, the writer, speaking of the treatment of contraction of the cervical canal and os uteri giving rise to mechanical dysmenorrhœa, and producing sterility, etc., in the chapter entitled "Of Straightness of the Matrice," says: "And when the places do seem to be softer to the feeling, then you must put a dry sponge, that hath a cord hanged at it, into the straight place, to the intent to make it wider, which, if it fall out, you must put in another that is thicker. Therefore, you must have many and sundry dry sponges ready." This ancient gynæcologist next refers to the possibility of these sponge tents producing inflammation in the mouth or neck of the matrice, and discusses its treatment, after which he continues: "When the inflammation is ceased, and the place is open, annoint upon a sponge or cerot made of oil of roses and goose grease, and use it untill it be healed, making the place a little sounder; but yet you must alwaies put in sponges untill

the end of the cure, lest that the mouth of the womb do gather together againe."

This coincidence does not extract from the merit of Sir James Simpson, to whom suffering humanity, as well as medical science, owes so much on other scores, as one of the first modern gynæcologists to make a practical application of tents in the treatment of a condition then commonly regarded as beyond the reach of curative treatment. I may, however, take this opportunity of observing that the number of such coincidences between long-forgotten ideas and so-called modern medical discoveries is far greater than could be readily credited by those who share in that illiterate neglect of the lessons to be gathered from the experience of the past, as embodied in the works of the older medical writers, and in that ignorant contempt for their opinions and observations which is, unfortunately, too prevalent at the present day.

It is not my purpose here to refer in detail to the successive improvements which have since been effected in the methods of carrying out the gradual dilatation of the cervical canal, the most important of which were due to the late Dr. Sloan, who introduced the use of laminaria tents as a substitute for the old-fashioned and now, happily, generally disused fœtid and inefficient sponge tents; and to Dr. Kidd, who improved on Dr. Sloan's idea by the employment of a number of laminaria bougies to secure a comparatively more rapid and complete expansion. Fortunately, we have now passed beyond the period of gynæcological practice in which these slow, painful, and often hazardous plans of cervical dilatation were the only methods available. No greater improvement has occurred in our branch of surgery than the replacement of these oftentimes unsatisfactory procedures by the more effective means now at our disposal for the rapid expansion of this canal. Of these, perhaps, the best known and most generally employed in this country are either Hegar's or Lawson Tait's dilators. I now desire to call your attention to another instrument which I have designed for the same purpose, and which, I venture to hope, may be found by others, as it has by myself, more satisfactory in its use in the treatment of dysmenorrhœa and sterility occasioned by stenosis.

This instrument will, I believe, be found to supply a want long recognised by gynæcologists—namely, that of a reliable and effective means of securing the rapid and permanent dilatation of the cervical canal in the treatment of stenosis giving rise to the morbid conditions now under consideration. The principles on which it is constructed differ from that of other dilators in several respects, and above all, in one which I consider most important—viz., in producing expansion of the canal from within, outwards—in other words, in imitating the natural process of expansion from the uterine cavity downwards to the os uteri; whereas other dilators, such as Hegar's etc., act in the opposite direction. In my own hands the utility of this instrument, the expansion effected by which may be determined and accurately measured by the affixed index, has been fully tested in a large number of cases of sterility and dysmenorrhœa in hospital and private practice. I may add that the instrument, which does not occupy more room than the ordinary sound when introduced, may also be used with advantage for the dilatation of the female urethra in many cases in which this procedure is indicated. This instrument has been carefully made in accordance with my directions by Messrs. Arnold and Sons, West Smithfield, London.

HEALTH RESORTS OF THE WORLD.

XVIII.—BOURNEMOUTH.¹

By REV. R. AUGUSTINE CHUDLEIGH,

LATE OF CHRIST'S COLLEGE, CANTAB., RECTOR OF WEST PARLEY, WIMBORNE.

BOURNEMOUTH has been said to have the mildest climate and the fiercest population of all the southern coast. That is not true. The climate is not so mild as that of Penzance or Falmouth, and the ferocity of its inhabitants has been considerably over-stated. Geologists assure us that the antecedents of Bournemouth were undeniably warm, and the meteorologists declare that its present climate maintains as much as can be expected of its ancient high-temperature traditions; for the tale of the strata below is of palms and great ferns, and creatures that love warm mud. The topmost stratum which at present overlies the rest consists of a busy mass of human drift which forty years of fashion's tide has been depositing around the mouth of that tiny burn which here struggles through the sand to the sea. It is said—but it is probably a malicious libel—that this burn-mouth was at one time an earthenware drain-pipe (and not very many inches in diameter), but at present the stream disappears into the earth on the landward side of the Pier-road. Whither it goes, or where it reappears, let no one be so profane as to enquire. That stratum of humanity, like the strata beneath its feet, is worth a little study. Its characteristic is diversity.

Bournemouth seems the chosen home of every class and every creed. Under its salubrious skies one sees the survival of the fittest, and the least fit, side by side. Gallant officers of both services—retired, of course—dyspeptic and pale clergymen, returned Indians, with hepatic troubles writ large on their sun-dried faces, seem to find life more tolerable here than elsewhere. *Omne quod exit* in 'ism, and *omne quod exit* in 'opathy can manage to exist. All the religions and all the diseases have their temples here, so that the sick in body and the sick in soul can enjoy unhindered their favourite cure. If these be somewhat combustible materials, and if, under the inflammatory influences of politics, religion, and temperance, they do occasionally catch fire, there is, of course, an opportunity for a little chaff about "ferocious populations." Yet, for all that, there are few places where religion is more real, or property more safe, where the Churches are more beautiful, or the congregations more earnest, than at the so-called "Hampshire Torquay." Why that name was given to Bournemouth is possibly known to those who gave it. The two places are not alike. The character of its fences is often a clue to the general character of a place. Now, Torquay abounds in limestone, and a mere boundary wall will often make one stop and admire it as an example of good and solid masonry. Bournemouth, on the contrary, is badly off for stone, but abounds in sands, mostly silicious; and the crumbling fences of sandy turf generally strike the new-comer as one of the peculiarities of Bournemouth. Perhaps it is not too much to say that the chief interest and importance of the locality (*absit omen*) is founded upon its sand. The dryness of its soil, the salubrity of its air, the interest of its geology, the peculiarity of its scenery, its flora, and that famous children's playground—its miles of soft beach, cannot be explained or

¹ In this series have already been included:—Florida, Santa Barbara, Spa, vol. iii., 1884; Bath, Tunbridge Wells, Monterey, Harrogate, Buxton, Leamington, vol. iv., 1885; The Mont Doré of Bournemouth, Matlock Bath, Malvern, Dax, Southport, vol. v., 1886; Hastings, Scarborough, Health Resorts of Scotland, vol. vi., 1887.

described without using the word sand with exceeding frequency.

Bournemouth lies in the Hampshire Basin, the westernmost of the three great eocene depressions which contain between them the best geology and the largest cities in the whole world. If one alights at the East Station and walks straight out to the East Cliff, the idea suggests itself that one is at the broken edge of a huge basin—that a large fragment has been broken off, or cracked out and washed away. At one's feet is a loose sandy cliff, the face of which is perpetually slipping and sliding downwards to the sea. It is not like the cliffs at the Land's End, which look as if they have never altered since Creation's dawn, and will remain unchanged till the final doom. It is not like the slates and schists of the Newquay coast, which look as if they were broken off fresh last night, and will lose their freshness by to-morrow morning. The Bournemouth cliffs more resemble a railway cutting, or rather, an embankment, not made *quite* recently, but channelled and gullied by a few years of frost and rain. What mean all these water-worn pebbles and sea-borne sands, and whence did they come? The geologist replies. And did he not give good reasons for his strange answer, we would not for one moment believe him. He declares that we are right upon the spot where the grandest of ancient rivers met the warm primæval sea. He tells of a vast continent which once stretched in continuous line across the Atlantic Ocean, though now Greenland, Iceland, the islands around Scotland, and the granite hills of Cornwall, are the only portions left above the waves. He tells us that the memory of this great continent still lives, not only in the traditions of Atlantis, and the Hesperides, but that certain migratory birds still select a line of flight which coincides with the ancient coast-line, as if impelled by transmitted habit to attempt an oceanic flight which grew gradually longer as the vanished continent sank beneath the waves. In consequence of this great barrier, the cold Arctic current could never chill the southern seas; while, on the other hand, the great Atlantic current would be curled round far more than now, and would pour its warm waters right into the estuary of the river which flowed down eastward from the Atlantis continent, with the result that just where Bournemouth now lies, there would be deposited vast beds of shingle, sand, gravel, and clay, in which would be mingled the fauna and flora of a continent and an ocean, of a fresh water river and a salt sea. Time would fail to tell of the ice age which followed, or of the great chalk barrier which in (comparatively) recent times joined the chalk of the Needles with the corresponding formation in Purbeck, near Swanage, just across the bay. How the sea and the land-springs combine to erode the cliff—the land-springs by forming an undercliff, as at Ventnor, the sea by promptly washing that undercliff away; how full five miles of land has thus been removed, and is being removed still—all this should be learnt on the spot by those who seek health, and health will assuredly be found in this process of seeking.

And Bournemouth has charms for others than the geologist. The botanist has a chance of finding many a prize. *Simethis bicolor*, found nowhere else in England, was found at Bournemouth so lately as 1855. And though an organised search revealed only "semi-detached villa residences" (eligible, of course) on the home where *simethis* grew, yet it is whispered that some know its retreat in Branksome Woods even now, and they don't mean to tell—and they are quite right, too. It is also said that *Diotis maritima* is occasionally seen on the tongue of land between the Avon and the Stour. *Carduus marianus* is within reach; at least,

there is a field where it regularly appears once every four years. It is the rotation of farm-crops which, by giving it a chance of growing, effects this periodicity. We know a bed, scarcely larger than a table-cloth, where *Cicendia filiformis* grows so thick that we once enclosed twenty-five flowers in one pinch of the finger and thumb. We found also a plant of *Centaurea solstitialis* with about three hundred buds on it, of which only four expanded, as it had to be transplanted to save it from the scythe.

Then there is Wimborne Minster and the Priory Church at Christ Church; there is the New Forest and Corfe Castle; there are the accumulated delights, on the earth and in it, of ten centuries and (say) ten billion years. The pier, the gardens, the clubs, and the trains, leave little to be desired. There are books published about Bournemouth as a health resort; and, like the place itself, they are "quite healthy and very dry;" but they tell one the analysis of the water, worked out to three places of decimals, and the curves of temperature accurate to the tenth of a degree. They tell for what diseases Bournemouth is indicated and contra-indicated, and much else which is useful to know, which is not found in this article; for this article strives to describe, not Bournemouth in a book, but Bournemouth out of book—how she felt, and looked, and pleased, as one roamed through her pines, was blown about by her breezes, got her sand in one's eyes, and personally made her acquaintance.

THE ETHICS OF PROVIDENT DISPENSARIES.

BY A. W. WALLACE, M.D.

It is the fundamental error of Socialism, that every individual claims a right upon the State for food, clothing, shelter, and medicine, and it is the condemnation of our Poor-law system that it has recognised this claim. The law is an universal one, that if anyone will not work, neither shall he eat. It rules in all its rigour in the lower creation. When autumn comes the drones in the bee-hive are ruthlessly thrust out, their wings bitten off, and they are left to die. Every creature must find for itself, and if it ceases to do so the penalty is death. It is a law most rigid in its application. It makes no exception on behalf of the weak, the aged, or the maimed. It says, Work or die. The human race is no exception to the operation of this law. There also it holds good—"work or die." Modern legislators have thought that they could reverse this law, and therefore they have enacted that men shall be fed, although they do not work. The consequence of this enactment is that, in order to prevent the State becoming bankrupt, it has become necessary to make poverty penal, so that, as Sydney Smith said, England is the only country where poverty is a crime. The penalty most usually enforced is that of imprisonment in a workhouse; but besides that, bullying and insult are largely used to lead to the provision made by the State being taken advantage of by as few as possible. The result of this has been the continuous demoralization of multitudes of people. The cause of all this has been that legislators have never understood that the operation of a natural law can never be successfully opposed. If in any case it acts injuriously the mischief can only be prevented by the operation of a higher law, which shall supersede the action of the lower. In the present case the law of kindness is the only one which can suspend the operation of the other. But "the quality of mercy is not strained." It cannot be administered by the State. It must be spontaneous. It must come as the free-will offering of cheerful givers. Sound wisdom must come

in to regulate the distribution of the streams, but only kindness can supply them. This must be the foundation principle on which both hospital and dispensary relief must be administered.

We pass now to the consideration of the practical rules which should regulate dispensaries, and shall take as our text a letter recently received from a medical officer of one which is considered a model. Our correspondent says: "That we do not get anything like proper remuneration for our work is plain enough; we however get rather better paid by it than from friendly societies, and there are two or three practitioners who have clubs at even lower rates than we get. One thing I have noticed—that some of my own private patients, who could and did pay a reasonable account, at once joined the dispensary. Of course I was a loser thereby. I have made a rough guess, and estimate that I get at the rate of ninepence for each visit; but then I have no dispensing or book-keeping for them, and all messages must be sent me before nine a.m., except in cases of accident or sudden illness. A good many of these cases are from among those who never would pay a doctor. It is a commercial transaction between the staff and the members. We work and they pay (though inadequately); but, as you say, the healthiest pay most in proportion. The same holds good in friendly societies. We could not go on at a profit here did the infirmary not allow us £500 a year for doing their outside work. As far as the members are concerned it is mutual help. Another evil I find is this, that as patients have not to pay for their medicine, many of them contract a mania for swallowing it. One patient I had never missed a month for four years in taking medicine, though she ailed nothing. We also have a long list of chronic cases and incurables." 1. It is evident that the entrance to provident dispensaries must be most carefully guarded, and for this purpose we would suggest a committee, composed of equal numbers of medical men, workmen's delegates, and representatives of subscribers. 2. There is a most important distinction between cases of severe and trivial illness which has never yet been recognised in its true financial bearing. Trivial cases are a large source of profit to the general practitioner, but they are the bane of dispensaries and of the out-door department of hospitals. For one case of severe disease, incapacitating a patient for work and demanding medical advice at his home, there are scores of cases where the patient can work all day and come in the evening for advice at a medical practitioner's surgery, paying 1s. 6d. for advice and medicine without any difficulty. Any arrangement by which general practitioners are deprived of these cases should be most vigorously opposed. On the other hand the care of a patient during a long illness, withdrawing him from work and requiring his being visited at home, does not pay the practitioner. We would therefore suggest for consideration whether a better-paid class of artisans might not be admitted to provident dispensaries for attendance during severe illness and at their own houses only; and that in slight illnesses they should pay for their advice and medicine in the usual way. 3. As the payments made by members cannot provide adequate remuneration to the medical staff, it is manifest that subscriptions must come from well-to-do people. In the general management of the dispensary as well as in the admission of members it appears to us that the three classes, the general subscribers, the working men, and the medical staff ought to be represented. 4. There ought to be provision made for dealing with chronic and

incurable cases and inveterate medicine swallows. The latter might be dealt with summarily by the committee submitting their case to two of the staff, and if found to be taking medicine without sufficient reason they could be removed from the list. The chronics and incurables might similarly be limited to a certain number of visits per month. 5. Provident dispensaries ought to be made a means of instructing the people in the laws of health. A system of district nursing ought to be in operation in connection with them, and lady visitors ought to assist in spreading a knowledge of the proper management of young children, and other matters of which the working classes are sadly ignorant. The medical staff ought also to do work in preventive medicine, and be *paid for it*. The only way to meet the downward tendency of medical remuneration is to get the working classes persuaded that cheap doctoring means, as a rule, bad doctoring. At present the working classes, and we fancy a great many of the non-working classes as well, swallow medicine as they would use a charm. They need to be educated. But when a great medical corporation declares that its members shall not instruct the public in the principles on which sound treatment is based through the press, it seems as if we must wait for better times, till the coming of the Coqigruers, or later.

Clinical Cases.

LEICESTER INFIRMARY.

A CASE OF TRACHEOTOMY.

By J. B. OKELL, M.R.C.S., L.R.C.P. (HOUSE SURGEON).

J. E. P.—, male, æt. thirty-four, was admitted on October 28th, 1887, at 7-45 p.m., suffering apparently from a slight difficulty in breathing. At 7-45 p.m., being summoned hurriedly to the ward, found him pulseless, and not breathing; so seizing a knife the trachea was at once opened, and a large silver tube inserted, which was held in place whilst artificial respiration was resorted to; after ten minutes he made his first gasp, so a hypodermic injection of ether (℥xv.) into his forearm, and an injection of brandy into rectum, were given. These had the desired effect, his breathing and pulse soon becoming very much better, consciousness however not returning until 1.30 a.m., being five and a half hours after the operation. In the after-treatment there was nothing noteworthy, as he went on well, making a good recovery, but always wearing a tube. His throat was examined about a week after operation, when he was found to be suffering from advanced tubercular laryngitis; but nothing abnormal could be made out in chest, his temperature being generally sub-normal, no cough, no sweating at nights; his slight expectoration on two or three occasions were carefully stained for tubercle bacilli, but none found. After nearly three weeks in bed he was allowed up, when he rapidly gained flesh. As he could not be taken into a convalescent home, he was detained here until January 24th, 1888, when he was discharged, still wearing his tube, which had been changed to a vulcanite one, being able to speak very distinctly. His throat was again examined, shortly before his discharge, when the disease was found to be stationary. I might add that he altogether denied having had syphilis, but anti-syphilitic treatment was tried without any appreciable change, for two months.

Remarks.—This case shows what can be done, even in apparently hopeless ones, by prolonged artificial respiration

and hypodermic injections of ether. I would call particular attention to the latter, as it caused almost instantly a revival of the pulse; and further, to the great benefit derived from constantly wearing the tube—firstly, as regards his voice, which had been in a whisper for over twelve months, but now being able to be heard some distance off; secondly, as to his bodily health, he now being able to do his work well, whereas before he had great difficulty in following his employment.

Reviews.

Notes on Surgery for Nurses. By JOSEPH BELL, F.R.C.S. Edinburgh: Oliver & Boyd.

It is often remarked that a good sermon to children is of more benefit to the adults present than the sermons addressed to themselves. On the same principle, medical practitioners may profit more by Mr. Bell's Notes for Nurses than by more pretentious treatises addressed to themselves. Anyway his papers are pleasant reading, and we nearly finished the book at a sitting, which is more than we can say for the majority of books we review. It is wonderful when all theories, and explanations, and controversies, and personalities, and claims to priority of discovery, are excluded from the pages of a book, how much may be put into 130 of them, especially when their contents are intended to recall the lessons that have been learned through the eye and hand at the bedside. Mr. Bell's book covers 132 small octavo pages, and the print is good; and yet the nurse who has mastered its teaching, not as cram but at the bedside, has got an amount of surgical knowledge which may enable her to relieve an untold amount of human suffering. In our opinion, high-class nursing is far more truly woman's vocation than ordinary medical practice, the more so that the surgeon is so rapidly invading the domain of the physician. Pott tells in his *Surgery* how in a case of fracture of the skull, with the usual symptoms of "Pott's tumour," the "physical gentleman," who was in attendance, objected to any interference, but the "physical gentlemen," now-a-days, are only too glad to have the cavities of the body which have hitherto been their exclusive preserves, explored, washed out, and otherwise interfered with by the surgeon. It is evident that in the immediate future there will be a demand for men in the profession considerably above the level of the ordinary medical practitioners. If the profession consisted of more highly educated men, and fewer of them, and if the public were once taught that, in the great majority of cases, good nursing is of more avail than swallowing physic, the result would be, that in place of the practitioner being a mere medicine vendor, selling his straw as a means of getting paid for his expenditure of time, he would be the superintendent and adviser in reference to the nursing arrangements; his visits would be less frequently required; he would be better remunerated for them, and he would have the knowledge and skill requisite for the performance of all the operations for preserving life which advanced surgery has introduced. But these reforms can never come from within the profession. They will only be the response to the demand of an educated public for something better than the present condition of things. We learn from Mr. Bell's book that he has laid aside the spray after many years careful trial of it, and now uses irrigation during dressing with a one-tenth per cent. solution of bichloride of mercury. It is curious that he does not

mention what mode of dressing he employs. One word in conclusion as to style. The author should make it more purely Saxon. We tested a very intelligent nurse with the *q.v.*, which he often uses, and she had no idea what it meant. A great many words from the Latin and Greek ought to be replaced by their Saxon equivalents. A. W. WALLACE.

The Diseases of the Ear, and their Treatment. By ARTHUR HARTMANN, M.D., Berlin. Translated from the third German edition, by JAMES ERSKINE, M.A., M.B.

THE frequency with which text-books on Diseases of the Ear, "for the use of students and general practitioners," have of late appeared, is a sign on the one hand of the increased interest now taken in this formerly neglected subject, while on the other it may be doubted whether the demand for such works is altogether commensurate with the supply; and we are inclined to think that the desire of the authors to put themselves *en evidence* counts for a good deal in the production of many volumes of this description. Be that as it may, the work before us will, we think, bear favourable comparison with most of its predecessors, and the author and translator are to be congratulated on the production of a very readable volume, which contains most of what the general practitioner needs to know on the subject of the ear. The book commences with an interesting historical sketch of the progress made in aural surgery from the time of Hippocrates to our own day, and the second chapter is devoted to the diagnosis of the various affections of the ear, as well as to the different methods of testing the hearing. It is to be regretted that rhinoscopy receives no attention at the hands of the author, for no book on the diseases of the ear is now complete without a description of this important method of diagnosis. The anatomical descriptions are necessarily somewhat meagre, and might possibly have been omitted altogether with advantage from a practical work of this kind, for, probably, few students will have recourse to them for their knowledge of the anatomy of the ear. In the treatment of polypi and granulations the author recommends perchloride of iron, nitrate of silver, and chromic acid. As regards chromic acid, we are glad to be able to corroborate all that the author says of its value, and we have never seen "severe inflammation produced by touching the surrounding healthy parts." In fact, we have found this agent so satisfactory that we have discarded all other caustics for the destruction of neoplasms, and with boric acid for the subsequent treatment of the purulent discharge, the terrors of a "running ear" have, to a very large extent, been removed. The illustrations and type are unusually clear and intelligible, and we can recommend the work as a reliable guide to the diseases of the ear.

RICHARD WILLIAMS.

Practical Manual of Diseases of Women and Therapeutics, for Students and Practitioners. By H. MACNAUGHTON JONES, M.D., M.Ch., etc. Third edition. London: Baillière, Tindall & Cox.

THIS work has followed the general law of evolution; the new edition bears only a general resemblance to the first one; it is enlarged and developed in those parts wherein most progress has been made, and it is now fully abreast with modern gynæcology. The second edition was admitted to be an improvement on the first; fortunately, the second edition was soon exhausted, and the third edition had to be prepared. Dr. Macnaughton Jones has evidently taken up the work of revision in this third edition with energy, and,

we might say as a labour of love: the result must be satisfactory to reader, author, and publisher. The great aim of the author has been to make the work practical and useful, and we can especially recommend the treatment suggested, for after all this is of paramount importance. In many works of this kind there is a hopelessness as to therapeutical indications, remedies are either ignored, or surgical aid is too readily invited. The judicious advice given will guide the practitioner in many a perplexing case. We thoroughly agree with the author that the practitioner who desires to practise his profession intelligently, ought to be able to make up his own mind, and to be able to give his patient his best advice, even though not a specialist. But no one can practise his profession at the present day with any degree of honesty, unless he is posted up in the lines of modern advance; hence the necessity for a manual of this nature. The work is well written, clear, and free from padding, and as it is profusely illustrated, we know of no book so suited to the modern requirements of the general practitioner.

Diseases of the Breast. By THOMAS BRYANT, F.R.C.S.
London: Messrs. Cassell & Company.

OF this addition to Messrs. Cassell's series of Clinical Manuals, it is only possible to speak in terms of the highest praise. From the distinguished position the author holds, his experience has necessarily been most extensive, and the whole literature of the subject has been consulted and condensed in this compact volume, bringing it well up to date (1887). The work consists of about 350 pages, and is illustrated with eight instructive and beautifully executed chromo-lithographs. The subjects for these chromos are well selected, representing, not types of rare diseases (except plate viii.), but affections and symptoms more commonly met with by the practitioner, such as "Submammary abscess," "Adeno-fibroma," "Cystic disease," "Dimpling and puckering of the skin in Carcinoma," etc. Plate viii. represents two rare forms of breast diseases—viz., "Chondroma" and "Hydatids." In all these plates the artist is peculiarly fortunate in the colouring. In the preface the author sets forth the object of his book as "a clinical exposition of the abnormalities and diseases of the breast, more particularly with reference to their diagnosis and treatment." An acquaintance with the microscopic, and macroscopic appearances of breast tumours is assumed, but the latter is fortunately not carried out, and much valuable information is given as to the naked eye appearances of the tumours on section. The work is lavishly supplied with cases; indeed the reader may be tempted to think too lavishly, but in a complete monograph of a subject this obviously cannot be helped, and on careful perusal it will be found that each case tends either to simplify a subject, or to emphasize the importance of a symptom. The first chapter is devoted to the anatomy of the breast, special attention being drawn to the suspensory ligaments, of which an excellent representation is found on the frontispiece. The second chapter deals with the "abnormalities of the nipple and breast," and is a concise *resumé* of all that is known of the subject. Speaking of hypertrophy of the mamma, many facts are brought forward throwing doubt on the accuracy of the general opinion that "increased function and therefore increased nutrition" are its chief cause. One of the best chapters in the book is that on chronic abscess, and the series (13) of illustrative cases in it well repay study. On the method of examination of the breast, the author's remarks are neither so full nor so clear as could be desired. Why too are they not assigned an earlier place? Thus chronic abscess often presents

great difficulties in diagnosis, yet this affection has been disposed of before the surgical student has been told how to examine the breast. As regards the method of examination, the inference to be drawn is that the practitioner or student should stand *in front* of the patient, and use *one* hand, a method not nearly so good as standing behind the patient and using both hands; thus: in examining the left breast, the right arm should be passed over the patient's right shoulder, and the left under her left arm, the palm of each hand being thus easily placed on the breast. The rare diseases of scrofulous and syphilitic mastitis have each a chapter devoted to them. Carcinoma is exhaustively treated in over one hundred pages. A wise suggestion is made that the term "encephaloid variety of carcinoma" should be abolished, as the disease is of extreme rarity, an error constantly arising between it and sarcoma. Whenever possible the statistics of cancer are gathered into a tabular form, and instructive tables are given of "Influence of Age" (analysis of 600 cases); "Duration of Disease when first seen"; "Duration of life in those operated upon" and "In those unoperated upon"; "Local recurrence after operation"; "Metastatic deposits," etc. On the much debated question of the removal of the axillary glands in every operation, as advocated by Mr. Mitchell Banks and Mr. Pearce Gould, the author lays down the following law: "The rule of practice ought, however, to be axillary exploration in the majority of cases of excision of the mamma for cancer, the omission of the practice, the exception." He thus allows himself a discretionary power, and evidently leans towards the older method of treatment; for a little later we find this warning: "The practice of exploring an axilla as a measure of routine, should not be followed, since it is without doubt a graver method to the patient, and the advantage which it in theory possesses is not yet proved." The opinion that "simple" cysts of the breast, if untreated, may give rise to solid growths and grave breast disease, is not one that will find favour with all surgeons. The writing is clear and pleasant, although the introduction of a word like "diagnostication," where "diagnosis" would serve equally well, is to be deprecated. The work may be confidently recommended both to student and practitioner, and will be found to well maintain the wide reputation of its author.

ARTHUR H. WILSON.

Short Notices.

The Scientific Enquirer and Journal of Microscopy.

AMONG our Short Notices in the January number of the *Provincial Medical Journal* we regretted to state that Mr. Alfred Allen, owing to the state of his health, had felt compelled to discontinue the issue of the *Scientific Enquirer*. This announcement, we have now the gratification to inform our readers, may be withdrawn. It had been received with so much regret, that the editor, who has met with many expressions of sympathy, and offers of literary aid, has determined to resume the publication of that useful periodical, with the skilful management, as publishers, of Messrs. Baillière, Tindall, and Cox.

We should add that the *Journal of Microscopy* commenced a new series on January 1st. The editor, Mr. Alfred Allen, relieved of the cares and details of publication, will be enabled to bring to the new series of the journal renewed energy, and the force of his long experience, in the direction of the Postal Microscopical Society from its first establishment.

W. B. K.

The Provincial Medical Journal,

APRIL, 1888.

THE French medical societies have of late taken up with considerable energy the much varied subject of the regulation of prostitution. The Société de Médecine Pratique has passed the following resolutions: 1. To create multiple dispensaries for venereal diseases, and to facilitate the means of treatment among the necessitous. Women to obtain, on request, cartes as to their state of health. 2. To suppress arbitrary imprisonment and obligatory visits. 3. To maintain liberty in the public streets by legal means.

At the Academy of Medicine, M. FOURNIER, who has been acting with a commission, has been vigorously defending some of the regulations now in force in France, though he is opposed to the present system of treating diseased women as prisoners. M. FOURNIER and many others who agree with him suggest more rigorous measures against solicitation in the public streets; at the same time they would relax the discipline in force at St. Lazare. M. BROUARDEL has pointed out at one of the debates that it would be extremely difficult to prove solicitation, and he asks How can it be defined, and Where does it commence, because it may even be conveyed by a glance of the eye? If arrests were numerous, only even twenty per day, it would require a special judge to try these cases; and even with a special judge there would be a difficulty, because witnesses would not care to appear. At the present time, in France, there is the utmost diversity of opinion between the most competent judges on the value of State regulation. In the *Journal de Médecine de Paris*, March 11th, M. A. MALECOT has an exhaustive article on "Venereans and the Common Law," and he thus sums up his conclusions: "We must aim," he says, "at diminishing the evil. It is caused by poverty, passion—by civilization itself. The remedy is to be found in the amelioration of misery, the moral training and protection of young girls, in the creation of refuges for unfortunate women, in facilities for work, and in education which shall develop a taste for family life. Such are the measures which legislators and philanthropists should employ. The duty of medical men consists in preventing the development of contagious disease. This is to be done by the popularization of measures of hygiene, by the care of the patients, and by the perfection of therapeutics. Those afflicted will submit voluntarily to treatment when there is no fear of imprisonment. By the multiplication of dispensaries, by opening the hospitals, by free advice, patients will be brought under treatment who would otherwise escape under a more rigorous *regime*." M. MALECOT says that he agrees with such men as STUART MILL, JULES SIMON, DUPONLOUP, PEPRESSENSE, DE LAVELEYE, HERBERT SPENCER, YVES GUYOT, that the violation of individual liberty is directly opposed to the end in view, for if the woman is threatened with sequestration she will avoid the police and continue her life under even more deplorable conditions. He advocates

the restoration of common rights to the women—the police to look after the public thoroughfares. The ideal system would be to isolate all syphilitics, but this is impracticable, because though the women might be arrested, yet the men, who are frequently as guilty, would escape, and they would in turn infect others. This is a most important social question, and so far from becoming simplified by the increasing experiences of centuries, and of different countries it is even becoming more complex. The regulation of vice in our large cities and towns is imperatively demanded, and the state of our streets in England is far from satisfactory. The recent discussion at the Academy of Medicine of Paris does not clear away the difficulties or show us how to effectually grapple with the evil. There is one old way, but it is so old that it will hardly find favour, because it rests upon teaching the authenticity of which will not be admitted. It is the teaching common to all Christians.

IN the last edition of his valuable manual on "Diseases of Women" Dr. MACNAUGHTON JONES says: "Individually, I never use intra-uterine injections. It may be prejudice and a dislike to run the unquestionable risks attendant upon their employment. I believe the less fluid we leave in the uterine cavity after any topical application the better. This applies with double force to the undilated organ. Metritis, peritonitis, collapse, colic, cellulitis, perimetritis, are more likely to follow the injection of fluids." It may not be without profit to compare the view of the English gynaecologist with that held by Americans, and we are enabled to do so as the question was well threshed out at a recent meeting of the New York Academy of Medicine. Some of the leaders in obstetrics and gynaecological medicine took part in the discussion, which was opened by the well-known Dr. PUTMAN-JACOBI. Dr. JACOBI recognised the objections against intra-uterine medication—viz., that they were dangerous, inefficacious, or superfluous, or all three together. She then examined the phenomena following on the use of caustics, to which she confined himself, as the purpose of the method was surgical, and for the removal of diseased tissue. Out of fifty cases under the author's care cure was produced in thirty-nine without accident; in five, accidents occurred, with one death. The conditions were different. Dr. JACOBI pointed out some of the dangers, amongst which none was so important as approximation to the menstrual period. The period of danger began ten days after the close of menstruation. Two applications in one month should not be made until the tolerance of one had been established. At the end of three months it was advisable to suspend the treatment for two months. In the majority of cases it was unsafe to make the application in the office and allow the patient to go, for she should remain in bed for six hours or six days. Intra-uterine medication should be regarded as a surgical operation, and as only one part of a complex treatment for uterine diseases. She had used iodized-phenol, carbolic and nitric acids. Dr. W. GILL WYLIE said he was pleased Dr. MARY PUTMAN-JACOBI spoke of this treatment as a surgical

one. He used intra-uterine medication a good deal, but always after keeping the patient for some time previously under observation for preparatory treatment. He always dilated if the uterus were contracted in the least. He was opposed to strong acids; cases were rare which required anything stronger than carbolic. Intra-uterine medication should never be adopted in acute cases. Dr. S. BARUCH agreed that this was surgical treatment. Four years before he read a paper on "The Therapeutical Significance of the Cervical Follicles," in which he endeavoured to show that all those diseases of the uterus classed under metritis, with or without catarrh, were most successfully treated by healing those follicles. His method was, when the disease was in the cervix, to open with a narrow bistoury and with a sharp curette destroy. He also treated intra-uterine catarrh with the sharp spoon. It seemed to him that thorough curetting was much more in accord with modern surgical ideas than the repeated use of caustics. Dr. P. F. MUNDE said that he thought the tendency was to drop the method. It was a surgical procedure, and dangerous, as might be the introduction of a sound, or even a digital examination, it therefore should be undertaken, with proper precautions, at the house of the patient if possible. There were three main indications for intra-uterine medication. (1) Intra-uterine catarrh extending from cervix to the fundus. (2) Subinvolution or hyperplasia, with or without catarrh, when it was desirable to reduce the size of the uterus, and then to control hæmorrhage. For many years he used milder agents, but he had to give them up. Finding that mild remedies did not answer, he had placed his patients in bed, dilated the canal, if necessary—not much dilatation being required in chronic uterine catarrh—so that the largest uterine applicator with a pledget of cotton would be readily introduced. He curetted with a dull instrument, and then swabbed the entire endometrium with a saturated solution of chloride of zinc, repeated two or three times perhaps, or until no bloody fluid oozed out of the uterine cavity. Then pack the vagina with iodoform or vaseline cotton. Keep the patient in bed two or three days, and apply an ice-bag to the abdomen for the first twenty-four hours. The next application was made at the office, but not within two weeks, and then a solution of one drachm to the ounce was used, or nitrate of silver of the same strength. The subsequent applications were made once a week. For hæmostatic purposes he curetted and then plugged the uterine cavity with cotton saturated with sub-sulphate of iron and glycerine, equal parts, and had never seen any bad results from this treatment. He attached a plug and removed it every twenty-four hours. Dr. CUSHIER said she had employed intra-uterine medication during the last ten years with good results. In dysmenorrhœa, in pelvic pain during the menstrual period, chronic metritis, subinvolution, and where there were reflex symptoms from pelvic disorder not due to either uterine displacement or ovarian disease, she used carbolic acid and iodized-phenol; the applications being made at the house of the patient, never after ten days subsequent to menstruation, and never within ten days

of the next period. In women who had not borne children she never resorted to intra-uterine medication until other means had failed. Dr. MALCOLM McLEAN said he narrowed down the agents to strong carbolic acid, using a ninety-percent. solution. Dr. BOLDT stated that he had been in the habit of making intra-uterine medications up to a few days of the menstrual period without accident; he did not employ strong caustics. Dr. A. F. CURRIER thought it important to keep in mind the fact that there was a great difference in the tolerance of patients, and therefore no fixed rule could be laid down applicable to all cases. He had seldom seen dysmenorrhœa benefited by such applications. In cases of hæmorrhage it was necessary to act at once. He used carbolic acid with iodine and a strong solution of nitrate of silver.

We have given the gist of the views of the various speakers condensed from a report in the *Therapeutical Gazette*. The conclusions we have drawn from a consideration of the report is that though, in the hands of specialists, intra-uterine medication has not been so disastrous as might have been expected, yet it is sufficiently surrounded by dangers, that Dr. MACNAUGHTON JONES' advice is judicious and one to be followed.

MOST of us have been brought up with the impression that lying-in women were specially liable to scarlatina, and were soon affected. This belief has received rude shocks from time to time, though it has never been definitely upset, and perhaps it is not well that it should be. The fear of disease is very often the beginning of wisdom, and it is well that women should have a dread of scarlatina, as it may lead them to take precautions to avoid it. At a meeting of the Obstetrical Society of London, March 7th, the subject came up for discussion through an admirable paper by Dr. BOXALL, a paper bristling with statistics, and bearing evidence of great labour and research. The experience of general practitioners who attend the majority of women in this country will, we think, bear out the statement we made at the meeting—that it would be impossible to practise midwifery if scarlatina were so easily taken by puerperal women, and that the precautions recommended are under existing circumstances impracticable. If general practitioners carried contagion there could not be a doubt as to what our duty would be. We should have to give up attending confinements if we had any scarlatina patients on hand, even though this would dislocate our practice. Change of clothes would not be sufficient unless we possessed princely wardrobes of unlimited proportions. We never could wear the same suit twice, even though we disinfected it—there always would be the possibility of some portion of the contagion remaining. The question settles itself, and we have an answer which defies argument. Speaking after twenty years of general practice, with an ample midwifery experience, and knowing the work done by general practitioners, we can positively state that scarlatina is not given by the practitioner to his patients. We know that numbers of men in busy practice have attended confinements even when

scarlatina epidemics have been present, and women confined during that time have not suffered. The experience of one man, or of one town or neighbourhood, is not sufficient to settle a question of this magnitude; we have much wider experience to guide us, we have but to consult the statistics for the whole country, and follow the scarlatina death curve. If puerperal mortality from scarlatina, septicæmia, and puerperal fever, runs up side by side with scarlatina, then there would be a strong argument in favour of the old view, but we find that the contrary is the case: while the scarlatina curve runs up, the puerperal curve runs on the same way. This fact was emphasized by Dr. MATTHEW DUNCAN when he said: "When scarlatina was killing 250 a week in London, there was no increase of puerperal fever."

Dr. BOXALL's paper opens out a very wide field for further investigation, not only on the communicability of scarlatina to puerperal women, but on the nature of the fevers from which women suffer after confinement. In the whole range of midwifery there is no more moot question than as to the nature of puerperal fever. Of course, we have numerous hypotheses and theories as to its nature, and we are able in certain cases to differentiate. One thing we may by a process of negative reasoning arrive at—viz., that puerperal fever, so-called, is not scarlatina in a disguised form. Of course, it is not to be denied that women do contract scarlatina *post-partum*. We know it by the symptoms, which are definite; but, as we have said, this is comparatively rare in proportion to the number of cases of women who develop a fever accompanied by offensive lochiæ, high temperature, prostration, and lowering of the *vires vite*, etc., a fever without rash or sore throat, or any of the usual accompaniments of scarlatina. It is a plausible theory that this class of case may be a masked form of scarlatina just as erysipelatous puerperal fever does not show well-marked symptoms of erysipelas. Here analogy, we think, is at fault. If puerperal fever be masked scarlatina, admitting the absence of rash and angina, we certainly should expect to meet, in a large number of these cases, with some evidence furnished by the kidneys to establish the relationship. It is remarkable how effectual treatment is in a large number of cases in which we have fever, high temperature, offensive lochiæ, etc. Flushing, with aired water or with some deodorants, appear to clear away local mischief. If scarlatina underlaid the conditions, we are inclined to think that the local injections would not be so beneficial, and it would be like sponging out a forty pound gun to remove a projectile lodged in the breech. We believe that the view of Dr. M. DUNCAN is the sound one, "that scarlatina is one thing, and puerperal fever another," the latter being an entity into which many factors enter.

MR. WELLER, sen., defined a dispensary as a place "where they gives you physic for nothing in your own bottles." There is a depth of humour in these last words. What would DICKENS have said had he heard of a dispensary where it

is alleged that the patients receive drugs made from methylated spirits, and where they have to pay for this precious stuff? We cannot vouch for the accuracy of this statement, but we have before us an account of a meeting of the Leicester Provident Dispensary, in which a charge of this kind is made. The Leicester Provident Dispensary, judging by the report, seems to us to demand a thorough overhauling, in view of the grave charges openly made against the management. This dispensary has long been held up before the profession as a model (?) and owing to its reported great success, institutions have been started in other towns, to the great damage and injury of the medical profession. Provident dispensaries may be written down as failures, though in a few cases they have benefited a few medical men and those officially connected with them. The Leicester Provident Dispensary during 1887 numbered 35,583 members, who contributed, according to Mr. HALLETT, £7,000. To manage this £7,000 and a dispensary, there is a manager who receives a salary of £710 a year. He is not a medical man, or even a chemist, and yet he is, as far as we can gather, responsible for the pharmaceutical portion of the dispensary. The most extraordinary part of the affair is that the members who contribute this respectable sum have no voice in the management of their own institution, and they actually allow subscribers, who give a small sum of £700, absolute power. We have always been under the impression that the working-men of Leicester were distinguished for their intelligence, but our faith is very much shattered by this instance of their trustful nature, and by their want of confidence in their own class. Now, however, they are moved through the exertions of the Rev. A. A. ISAACS, Vicar of Christ Church, we shall expect them to fight this matter out to the end, and secure representation proportionate to taxation. They have indeed a strong champion in the vicar, as he was able to present a memorial in favour of reform, signed by the leading medical men in Leicester, Drs. MARRIOTT, BENFIELD, NEALE, POPE, CLARKE, DENTON, JOHNSTON, MACALEVEY, BRYAN, GREASLEY, BARLOW, BENNETT, DODD, LITHGOW, STEWART, MOORE, DOUGLAS, BOND, SLOANE, COOPER, LANKESTER, CLEMENTS, SNOAD, EMMERSON, and THOMPSON. We feel sure that by perseverance the present Committee will be compelled to yield to the wishes of the members, and institute an independent inquiry. The tactics pursued in London at one of the special hospitals will hardly do for Leicester. The London Board tried to ignore the grave charges made against the secretary and manager, and it would seem that the Committee at Leicester have taken a leaf out of their book. Mr. LABOUCHERE has challenged the London manager, and invited an action for libel, but the outraged person has not taken up the challenge. The Rev. A. A. ISAACS at Leicester, supported by a Committee, has made grave charges against the management of the Leicester Dispensary, but the Board in place of taking up his challenge, decided to ignore them, and rejected his very reasonable proposal, that Drs. MARRIOTT and BENFIELD, himself,

and five other members who waited on the Board, should join the Board for the purpose of investigation. We have mentioned the salary received by the manager, who does not confine his attention purely to the dispensary, but who follows other avocations. We have not seen what remuneration has been received by the medical officers of this model provident institution. 35,583 subtracted from the population of Leicester and the neighbourhood make a very considerable inroad into the *clientele* available to those practitioners who have to live by their profession in Leicester, and here the injury to the profession generally is experienced. The 35,583 do not pay an adequate rate, and if the principle of this form of contract were carried out in the trades to which the workpeople themselves belong, there would very soon be a strong outcry against it. Medical labour seems to stand on a basis of its own, and its provisions to rest on a violation of the ordinary laws of political economy. The plea of poverty is raised by philanthropists, and by promoters on behalf of the working man, and the provident dispensary is the outcome. Who does it provide for; who is it provident for? Experience tells us that the medical men attached to these dispensaries earn a wage that even scavengers would reject, it does not provide for them or their families. Does the working man even gain? Does he obtain the best advice, and the best drugs? or has he to content himself with medicine furnished in his own bottles; or to take drugs made of methylated spirit, or putrefying infusions of quassia and gentian. It is possible to obtain even medicine and medical advice too cheaply. The Leicester institution does certainly provide for one person. The position of the model provident dispensary of England, with its secretarial manager at £710 a year, after twenty years of life, is not calculated to strengthen the confidence of the profession in this class of institution; and when it is possible to have such allegations made against a dispensary which claims to stand in the first rank, what shall we say of the condition of the numerous other institutions of the same kind scattered over England?

Annotations.

“Forsan et hæc olim meminisse juvabit.”

THE LATE EMPEROR OF GERMANY.

THE Emperor is dead! Long live the Emperor! We heartily join in the last wish, and hope that the Emperor may be spared after what he has already suffered, not only through his illness, but through the surroundings of it. We have been told that the Emperor read what was published in the papers about him, and it must have been very unpleasant reading, especially if he saw some of the papers, in which it was stated that he was suffering from syphilis, and that he was improving under the use of iodide of potassium. We should congratulate him if the very first action of his reign were, to issue an Imperial Ukase that his own case should not be discussed in any German medical

paper, and that his own physicians should refrain from publishing a single line, except an official bulletin, counter-signed by one of his officers of state. *Le Secret medical* is inviolable in France, the meanest subject is protected by it; damages can even be obtained for its violation. The unseemly criticisms of a portion of the medical press, and some eminent professors, is detrimental to the best interests of medicine. Sir Morell Mackenzie has had no ordinary case to deal with; almost the responsibilities of an empire rested on him, and we believe he has borne himself all through with a dignity worthy of his responsibilities. The general principles involved in this case affect every practitioner in the kingdom, and if the tactics pursued against Sir Morell Mackenzie were adopted in English life, the practice of medicine would be more arduous than it is. Emperor, King, Queen, even Commoner, have a right to choose their own medical adviser; when in each individual case the adviser has the confidence of his client, we cannot admit the right of outsiders to interfere. When other consultants are sought, and a difference of opinion is expressed, it rests with the patient to decide as to what advice shall be accepted. The responsibility of treatment rests upon the person or persons selected. The best ethical principles have been laid down on the attitude of those whose advice has been rejected; they have to give up the case, after stating their disagreement, which is purely a matter for the patient's relations. We have all along laid down the dicta that the question at stake rises far above personalities, and we trust that some good may come even out of the discreditable performances of disappointed specialists.

THE UNIVERSITY OF LONDON AND THE NEW CHARTER.

At a meeting of Convocation of the University of London, March 6th, the following resolution was carried by a large majority—viz., “That Convocation desires respectfully to express regret that the Senate has not seen fit to take action against the petition to the Crown of the Royal College of Physicians and the Royal College of Surgeons for a charter enabling them to confer degrees in medicine.” There is a diversity of opinion between the Senate and Members of Convocation.

THE BACILLUS OF CANCER.

M. RAPPIN, in the *L'Union Médicale*, states that he has separated the bacillus, or micrococcus of cancer, closely resembling the micrococci met with in suppurating surfaces. This bacillus M. Rappin describes as a diplococcus, consisting of two more or less regular spheres, the point of junction of which does not take the aniline dye. They have been found in sections of the cells and alveoli of cancer, and have been successfully cultivated in sterilised gelatin. Inoculation of a rabbit with this culture was followed in three months by cachexia and nodules of malignant disease. Portions of these nodules gave under culture the same diplococcus. They have subsequently been found in the blood. Further researches are however required.

A WISE SCHEME.

THE School Board at Baltimore, Maryland, are leading the way in a practical measure of school reform. They have requested the mayor and city council to authorize the appointment of a physician, who shall be known as the Sanitary Superintendent of Public Schools, whose duty shall be—(1) To examine carefully all plans submitted for the construction of new schoolhouses, and suggest such modifications as may be necessary from a sanitary point of view; (2) to advise with the Commissioners with reference to necessary alterations in school buildings to improve their hygienic condition; (3) to examine all text-books before adoption, in order that type, printing, or paper injurious to the eyesight of pupils may be avoided in selecting such books; (4) to satisfy himself, by personal experience, if necessary, that all pupils admitted to the schools have been properly vaccinated, or are otherwise protected against small-pox; (5) to take such other measures, in conjunction with the Health Commissioners of the city, as may be necessary to prevent the spread of contagious diseases in, or through the medium of the public schools; (6) to examine annually the eyesight of all children attending the public schools, and keep an accurate record of such examinations; (7) to report annually, or as often as may be required by the Commissioners, upon the sanitary condition of the schools, and of the pupils attending them, and to advise the Commissioners upon sanitary questions connected with schools whenever required; (8) to give instruction, by lectures or otherwise, to the teachers in the schools upon the elementary principles of school hygiene.

THE IMPROVEMENT OF BRITISH HEALTH RESORTS.

WE have endeavoured, and with a certain degree of success, to bring into prominence our English health resorts, and we have described the climate of Harrogate, Bath, Buxton, Leamington, Hastings, Scarborough, Southport, Lytham, Tunbridge Wells, Matlock, Malvern, Bournemouth, Woodhall Spa, etc. We must admit that a great deal has yet to be done before we can compete with foreign watering places. In the first place, the cost of living will have to be reduced. Even allowing for the expense of travelling and bath taxes, it is cheaper to go abroad. What is evidently wanted in England is a greater attractiveness. We thoroughly agree with Dr. Drummond, Rome (*British Medical Journal*, March 10th):—"There are many south coast sanatoria which, if properly developed, would often enable the invalid to remain in England. My own experience, while practising in Devonshire long ago, convinced me of this; but for the completeness of such, an entire reorganization, by the establishment of winter gardens, pleasure grounds, baths of various kinds, libraries, and really good cheap music, would almost in any case be required. It is incomprehensible to me that some such organization as that at Carlsbad, which, with certain local modifications, exists in every spa in Germany, should not long ago have been applied in England."

THE INDIAN MEDICAL SERVICE.

THE influence of the Medical Service in India has never been as fully (or as deservedly) recognized as it ought to have been. Our Indian medical officers by their work have become civilizers, and helped to consolidate the empire. We are not surprised at the *Indian Medical Gazette* making the following statement:—"Wherever English dominion extends, or whatever mission is undertaken beyond the boundaries of English rule, the dispensary accompanies or follows the occupation or sojourn of our officers, and the inhabitants flock to it for succour. The political importance of this remarkable feature of our conquests, annexations, and expeditions in the east, has frequently been pointed out by military and political officers, and we have recently had the gratification of reproducing the emphatic testimony borne by a distinguished soldier and administrator, Sir Neville Chamberlain, to the help which Indian medical officers, serving on and beyond our frontiers, have rendered in reconciling turbulent and suspicious races to our rule. This influence is now being carried into effect in Beluchistan and Burmah, and we have no doubt that the present generation of Indian army surgeons will fully sustain the reputation for humanity and skill gained by their predecessors."

"ROUGH ON RATS."

THIS is the name of a vermin destroyer. We learn from the *Australian Chemist and Druggist* that it is used as a favourite method of suicide in the colony. The following chronicle tells its own tale:

At Sydney, on December 15th, a woman named Emma Smith unsuccessfully attempted suicide with "Rough on Rats."

At Invercargill, on November 29th, an old resident named John Vint, engaged as a hawker, committed suicide by taking "Rough on Rats." At Wellington, on November 26th, Mrs. John Martin used the same poison to end her life. The vomiting it caused was attributed by her husband to drink, and no medical advice was obtained. The verdict was temporary insanity, joined with a severe censure on the husband for his neglect.

At Sydney, on December 9th, Mrs. Mary J. Joyce committed suicide by taking "Rough on Rats." An intemperate woman named Mrs. Annie Upton committed suicide on November 30th, at Sydney, by taking "Rough on Rats."

On December 5th, at Hobart, a stonemason named William Joseph Gillon committed suicide by taking a solution of "Rough on Rats."

Is it not time for Government interference?

EXTERMINATION OF RABBITS IN AUSTRALIA AND NEW ZEALAND.

M. PASTEUR's plan for the extermination of rabbits in Australia and New Zealand, where these animals have multiplied to such an extent as to have become a plague, is to water the herbage with decoctions of the chicken-cholera-culture. The rabbits are prone to take the disease which is fatal to them, and they die by hundreds in their burrows. An account is given in *L'Union Medicale* of a trial of this plan upon the property of a lady at Reims, attended with full and perfect success. We await with interest the proceedings in Australia, whither M. Pasteur's delegates have gone.

THE UTERUS IN THE LAST MONTH OF PREGNANCY.

At a meeting of the Obstetrical Society of Philadelphia, February 2nd, Dr. Hamill exhibited a uterus removed from a woman in the last month of pregnancy. The uterus was removed about twenty-four hours after death. "I was present when the patient died, and wished to remove the uterus immediately, but could not obtain the consent of the family. I shall very briefly call attention to the several conditions noticed: The outer surface of the uterus is studded in many places with syphilitic nodes. The woman had contracted syphilis early in her married life, and manifested other marked symptoms of the disease. There is also a small cyst of the broad ligament. The specimen presents quite markedly the contraction ring, or ring of Bandl. I give both designations advisedly, inasmuch as it is not definitely determined whether this ring represents the internal os, as Bandl asserts, or marks the boundary between the upper and lower uterine segment, as Schröder believed. According to the investigations of MacDonald, Müller, Sängner, and Lusk, this condition does not always exist. In three autopsies made by Lusk he failed to find any trace of Bandl's ring. Schröder, in a frozen specimen, found this ring very distinctly, but claimed that it was the dividing line between the upper and the lower uterine segment. Bandl holds the contraction ring of Schröder to be the true internal os, and consequently one would expect to find below this ring the cervical mucous membrane, whereas the portion between Bandl and Müller's ring is covered by decidua. Bandl explains this by his three hypotheses: (1) the deciduous membrane is crowded down into the cervix by the weight of the presenting part; (2) in primiparæ the advancing head strips off the mucous membrane, which is replaced by decidua; (3) the cervical mucous membrane is transformed into decidual membrane during pregnancy. Another interesting feature, which the specimen demonstrates beautifully, is that condition pointed by Leopold and Lusk as seen in their Cæsarean sections—viz., the delicate filamentous bands running from the chorion to the decidua, which are the atrophied villi of the chorion. The attachment of the placenta is to the posterior wall of the uterus."

THE MUSICAL PRODIGY, JOSEF HOFMANN.

This boy is much to be pitied, looking at the fate of other prodigies. The state of his health, according to the American medical journals, is attracting attention, and we hope that the little man will not be taken for some time on tour. He is ten years and a half old, and weighs about sixty-three pounds. According to the *Medical News*, Philadelphia, he performed at his last concert a long concerto by Beethoven, with orchestra; a polonaise with orchestra, a duet with harp, an improvisation, and four solos. He says that he was very much fatigued after this concert, which occurred in the evening. He urinated freely after each piece, and wet his clothing while performing. He complains that he is much fatigued by travelling. He plays with toys, etc., like other boys of his age, but much of his time is

taken up by a certain amount of work which he has to do in public. It is evident that his concerts have become irksome to him, although his intense love of music is undiminished. If the boy is taken on tour, there cannot be a doubt that the number of pieces should be cut down, and he should have ample time for rest between his public performances.

POISON IN HAIR DYES.

LADIES will use hair washes and dyes, and other toilet product, to make themselves beautiful. They resort to the advertised vegetable hair dyes, which are supposed to be harmless. The *American Druggist*, January, gives us some examples of these vegetable dyes. "Eau des Fées" is a solution of sulphate of lead in hyposulphite of soda. "Eau Figaro" consists of three solutions: (1) nitrate of silver and sulphate of copper; (2) sulphide of sodium; (3) cyanide of potassium (to remove the silver stains). "Eau des Fleurs" is composed of rose water, 95.5; flowers of sulphide, 2.7; acetate of lead, 4.22; sulphuric acid, and camphor. Passing to cosmetics: "Lait de Ninon" is composed of bismuth and zinc; "Eau de Castille" of hyposulphite of soda and acetate of lead. Pomades against baldness all contain cantharides and croton oil. So ladies had better beware; there is danger in trying to be beautiful for ever.

THE VICTORIA INFIRMARY, GLASGOW.

THIS hospital seems now to be fairly under weigh. The constitution will shortly receive the sanction of Parliament, and the legal difficulties which were in the way of a sum of £10,000 being added to the building fund seem to be surmounted. If all goes well building operations will be begun in April. The committee who have had the framing of the constitution have made a departure which will have important results by giving working men direct representation on the board of management. It still remains, however, to fight the battle against "subscribers' lines." In both the other Glasgow hospitals it is necessary for admission to get an order from a subscriber of one guinea or upwards. The result of this arrangement is, that not a few persons get admission to the hospital who have no right to its privileges, and on the other hand many cases of acute disease are excluded from the difficulty of getting orders. It appears, however, as if the abuse is likely to die hard.

GENERAL MEDICAL COUNCIL AND UNQUALIFIED PRACTICE.

At a meeting of the Executive Committee of the General Medical Council, the following report was adopted:—"A registered medical practitioner would render himself liable to the censure of the Medical Council in case of the employment of an unqualified assistant in the practice of medicine, surgery, or midwifery, on behalf and for the benefit of such registered practitioner, either in complete substitution for his own services, or under circumstances in which due personal supervision and control are not or

cannot be exercised by the said registered practitioner. The Executive Committee furthermore take this opportunity of stating, in reference to the procedure known as 'covering,' that in its view a registered practitioner covers an unregistered person when he does, or assists in doing, or is party to, any act which enables such unqualified person to practice as if he were duly qualified."

THE NEW ROYAL WARRANT.

VOLUNTEER surgeons should carefully read and digest the following Royal Warrant:—

ROYAL WARRANT.

ESTABLISHMENT OF ARMY MEDICAL RESERVE OF OFFICERS.
VICTORIA R.

Whereas We deem it expedient to provide for the establishment of an Army Medical Reserve of Officers:

Our Will and Pleasure is that the following shall be the conditions under which the said Reserve shall be formed:—

1. The ranks of Officers of the Army Medical Reserve shall be those of Surgeon-Major and Surgeon.

2. Medical Officers of Our Militia, Yeomanry Cavalry, and Volunteers, who may desire and be permitted to join the Army Medical Reserve of Officers, shall undertake to perform Army duties at home under rules to be fixed by Our Secretary of State, and to act under the orders, for administrative purposes, of the Director-General of the Army Medical Department.

3. Acting Surgeons, and Honorary Assistant Surgeons, of Volunteers may be permitted to join the Army Medical Reserve of Officers if they have passed the prescribed examination for proficiency.

It is Our further Will and Pleasure that the rank of Surgeon-Major shall be conferred on those Surgeons of Our Auxiliary Forces who may desire and be permitted to join the Army Medical Reserve of Officers on completion of 12 years' service from the date of their first appointment to the Auxiliary Forces; and also that Acting Surgeons, and Honorary Assistant Surgeons, of Volunteers permitted to join the Reserve shall be granted the rank of Surgeon therein.

Given at our Court at Windsor, this eighteenth day of February, 1888, in the 51st year of Our Reign.

By Her Majesty's Command,

EDWARD STANHOPE.

Secretary of State's Instructions on the foregoing Warrant.

1. No Medical Officer of the Auxiliary Forces shall be appointed to the Army Medical Reserve who is not medically fit for service, and whose character and qualifications are not in all respects satisfactory.

2. The names of all Officers of the Army Medical Reserve shall be included in a special Army Medical Reserve List.

3. Officers shall be removed from the Army Medical Reserve List on attaining the age of 65.

4. Officers of the Army Medical Reserve shall be liable to be called to Army service at home, in times of great national emergency, to take the place of such of the Medical Staff of the Army as may be withdrawn for active service, and when so called out shall receive the pay and allowances of their rank.

5. Medical Officers of the Auxiliary Forces who may be permitted to join the Army Medical Reserve shall undertake to accept the charge of the Officers and men of any detachment of troops, not having an Officer of the Medical Staff attached to it, at any station at which they may reside, with the rates of remuneration laid down in Art. 354 of the Royal Warrant for Pay, etc., 1887.

6. Officers of the Army Medical Reserve who are willing to offer their services will have a prior claim to employment in the district in which they reside to other Medical Officers of the Auxiliary Forces, or to civilian medical practitioners.

7. The acceptance of appointments in the Army Medical Reserve

will in no way modify the position of Medical Officers in the regiment or corps of the Auxiliary Forces to which they belong.

8. Officers wishing to apply for appointment to the Army Medical Reserve will forward their applications, through the Officer commanding the corps to which they belong, to the General Officer commanding the District, for transmission to the Military Secretary.

New Materia Medica.

Anthrarobin is the name given to some new compounds which are being sent into commerce for the treatment of skin diseases. Some time since, in attempting to reduce chrysophanic acid to chrysarobin Professor Liebermann found that this change could not be effected, the reduction taking a different direction, and a body being formed in which one atom of oxygen was replaced by two of hydrogen, but nevertheless yielded chrysophanic acid on oxidation. In following out his researches on other colouring substances of the anthraquinone group, it was found that alizarin, anthrapurpurin, anthragallol, flavopurpurin, and other allied compounds, yielded similar reduction products, which have the same property of rapidly absorbing oxygen, and reproducing the body from which they were reduced. Professor Liebermann, believing that the value of chrysophanic acid is chiefly due to its power of absorbing oxygen, considered that the physiological action of these bodies would probably be similar in character to that of chrysophanic acid. This idea has been proved to be correct as regards some of the new bodies, Dr. Behrend reporting that the alizarin product is effective in all cases in which chrysarobin has given relief, to which, however, it is somewhat inferior, though more active, than pyrogallol acid. It is the alizarin product which is at present offered in commerce under the name of anthrarobin; the allied product derived from purpurin being, however, also in use, but distinguished by the addition of the letter P or F. Anthrarobin is a yellowish white powder, tolerably stable in the air if kept dry. It is not soluble in water or aqueous acids, but readily soluble in dilute alkaline solutions with a brown yellow colour, such solutions absorbing oxygen with avidity, and passing through green and blue to alizarine violet. It is less easily soluble than chrysarobin in benzol and chloroform, but dissolves more readily than it in alcohol. It is also soluble in glycerine. It is made by boiling commercial alizarin or purpurin with zinc dust and dilute ammonia solution, filtering off the ammoniacal solution into hydrochloric acid, and collecting, washing, and drying the precipitate. The commercial article yields about $\frac{1}{3}$ per cent. of zinc ash. The advantage claimed for the new product by Dr. Behrend is that it produces no inflammation of the cuticle. It colours the skin slightly brown, but the stains can easily be removed from linen or cotton by soap and soda.

a-Naphthol is now put forward by M. Maximovitch as an antiseptic, possessing the advantage over β -naphthol of being three times less poisonous. It is insoluble in cold water, but dissolves in water at 70°F., to the extent of four parts in 10,000, the solution being of a violet colour. It is, however, readily soluble in alcohol and ether. Its antiseptic property has been tested by M. Maximovitch on fourteen different kinds of microbes cultivated in different media. When added to cultivation in bouillon, in the proportion of 0.1 part per 1,000, it completely arrested the development, among others, of the microbes of glanders, chicken cholera, pneumonia, the bacillus of typhoid fever, and the organisms of suppuration *Staphylococcus albus* and *S. aureus*. For cultivation in agar-agar the proportion necessary was somewhat larger in certain cases. Urine after being shaken with an alcoholic solution of *a*-naphthol did not ferment.

Ophioxylon serpentinum, an East Indian plant belonging to the natural order *Apocynaceæ*, has been examined by Professor Bettink, of Utrecht, who has obtained from it a crystallizable substance, to which he has given the name of ophioxylin. It forms orange yellow crystals, of the tetragonal system, having an acrid burning taste; slightly soluble in water, more so in alcohol, and freely in chloroform, benzol, and

carbon bisulphide. The root also contains volatile oil and resin, and a tannin which occurs in a natural combination with the opioxylin.

Cytisine, the active principle of laburnum, and found also in other species of cytisus, has been found by Dr. Kraepelin to be very valuable in some forms of migraine, especially when due to a dilated condition of the blood vessels; this active principle acting powerfully as a vaso-constrictor. In a case in which violent attacks of migraine were associated with vomiting, sleeplessness, photophobia, swimming of the eyes, and unbearable hemicrania, and in which all ordinary remedies had proved useless, the subcutaneous injection of 0.003 gramme of nitrate of cytisine had an immediate effect. In subsequent attacks, it produced a similar good effect, except once, when it was administered by the mouth, and caused immediate vomiting. The dose was ultimately increased to 0.005 grain. In cases where the migraine was accompanied by a good deal of spasmodic action, it had a negative, or even an injurious effect, so that it can only be recommended in migraine of a paralytic type.

Delphinium Consolida has long been known to possess anti-scorfulous properties, but has not been used in this country for many years. Like convallaria, and other valuable remedies which had fallen almost into desuetude, delphinium is now receiving the attention in Russia that it probably deserves. Dr. Krasnogradoff has directed the attention of the Caucasian Medical Society to the value of the plant in scrofulous affections, he having obtained successful results from its use.

In an original communication to the *Medical Bulletin* (January, page 10), Dr. S. T. Landry speaks of the value of *Nabalus altissimus* in a case of traumatic gangrene. In the case which came under his notice, the leg was black, and the patient sleepless and wild with pain. The leaves were washed and applied all round the limb, and left there for twelve hours, almost instant relief to the pain following the first application. After removal, damp tobacco leaves were applied for two hours. In two weeks the leg was healing, and comfortable.

Dr. Landry has equal faith in the value of *Inula Helenium* for the treatment of elephantiasis, for which, he states, it is a specific, if ever there was one. The affected part is bathed in a strong decoction of the fresh root every day for two or more weeks, two to six ounces of the decoction being also taken internally three or four times a day. He states that it never failed to cure in every case when properly used and thoroughly applied. Its value most probably is due to the antiseptic properties of the helenin, which has already been stated to be fatal to the *bacillus tuberculosis*.

Another plant which does not previously appear to have been used medicinally, but which is recommended by Dr. Landry, is *Zinnia elegans*, a favourite garden flower in this country. He states that the bruised petals, mixed with wood ashes, eased the pain of burns as if by magic. In this case, however, some of the credit is due, without doubt, to the alkaline character of the wood ashes, which would produce the same effect as carbonate of potash or soda.

A new artificial alkaloid has lately been discovered, to which the name of *Oxy-propylen-di-iso-amylamine* is given. It is prepared by the action of hydrochloride of propyl on di-iso-amylamine. It forms an oily colourless liquid, only slightly soluble in water, but soluble in alcohol, and forming very soluble salts with acids. The physiological action of this body has been investigated by E. Louise. On the nervous system it acts something like atropine, but in toxic doses causes epileptic seizures of two kinds. In moderate doses it is a powerful cardiac tonic, and an energetic stimulant of the circulation, and the cerebro-spinal centres. In its action on the heart it resembles atropine, paralysing the inhibitory apparatus, and increasing the action of the accelerating nerves. There is remarkable augmentation of the intra-vascular pressure, and marked elevation of the temperature of the body in cases of acute intoxication. The toxic dose for a man weighing sixty-five kilogrammes is thirteen grammes.

Grandiflorine is the name given to a new poisonous alkaloid discovered by Dr. Domingos Freire, of Rio Janeiro, in the fruit of *Solanum grandiflorum* var. *puberulentum*, known as wolfspear, or *Fruito do lobo*. The alkaloid has a bitter taste, but the quantity as yet prepared is insufficient for a complete investigation. The plant from which it is obtained is, however, known to be speedily fatal to sheep.

New Remedies.

Antipyrine has been tried by Sonnenberger in whooping-cough with favourable results in seventy cases. The dose given to young infants is half a grain to one and a half grain three times a day. For older children the dose may be increased up to fifteen grains. The syrups of tolu and orange are recommended as agreeable media for administering the drug. According to Fraty, antipyrine has an influence somewhat like that of the alkaline bromides, in some cases of epileptic convulsions; but large doses are necessary—viz., as much as three to eight grammes every day. In some cases the remedy causes malaise, and has to be discontinued.

The value of *pyridine* in asthma has been confirmed by Relemen, who has tried it extensively in diseases of the lungs and heart. In nineteen cases the vapour acted energetically as an anti-asthmatic, half a drachm or so of the liquid being allowed to evaporate at some little distance from the patient. In emphysema the improvement lasted from eight to twelve hours, but the most beneficial effects of the drug were seen in cases of cardiac and nervous asthma.

Dr. J. T. P. McConnell points out in the *Practitioner* (February, p. 95) some new uses of *Cannabis Indica*, or at least uses which appear to have been overlooked or neglected in this country. In Bright's disease, dyspeptic diarrhoea, or loss of appetite consequent upon exhausting diseases, he found it of great use; also as an hypnotic in chronic cardiac disease. He considers the value of the tincture depends to a considerable extent upon its being prepared from the fresh plant in India. This may be so, but it has been pointed out by Dr. Watt that the strongest kind of the drug, which is in the form of cylindrical (not flattened) tops, rarely, if ever, comes to this country.

Cascara sagrada would probably be much more extensively used were it not for the great bitterness so frequently found in preparations made from it. A method of removing this bitterness without interfering with the medicinal properties of the drug has been suggested by M. Granger, of San Francisco. This consists in mixing thoroughly one pound of coarsely powdered cascara sagrada with a magma of an ounce of calcined magnesia, and ten ounces of water, packing the mixture in a percolator, and allowing it to stand twelve hours before percolation with alcohol. The product is said to be free from bitterness, and to have an agreeable, mild, somewhat astringent, taste; while it is equally as active as the bitter preparation. From an examination of the bark made by Messrs. H. T. Meier and J. Le Roy Webber, it appears that the aqueous extract of the bark has naturally an acid reaction, and that if kept, it becomes increasingly so, giving rise to a precipitation of the resins. In an alcoholic solution, although the same changes may take place, the resin will naturally remain in solution. The decomposition that takes place in the bark is due to a ferment, precipitable by subacetate of lead. This ferment, according to the author, develops vegetable acid from the glucose present in the bark, and the acids so developed, decompose a glucoside present in the bark. It is to the decomposition of glucoside that the authors attribute the bitterness of the fluid extract, and the tonic properties it possesses, the laxative action being due to the resins.

Strophanthin, the glucoside obtained from *Strophanthus Kombe*, is stated by Dr. Dujardin-Beaumetz to be deficient in the powerful diuretic action produced by the tincture of the seed.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

Salicylic Acid in the Treatment of Herpes Tonsurans (*Der Fortschritt. Genf.*, February 5th, 1888).—A solution of one part in ten of salicylic acid in alcohol, applied daily, will effect a cure in from eight to fourteen days. This solution reaches the pores of the skin, and sheathes of hair, more rapidly and more effectually than any medicated ointment.

Unroasted Coffee a Remedy in Migraine (*Der Fortschritt. Genf.*, February 5th, 1888).—The medical profession, and the people generally, in the Antilles find the infusion of green coffee, taken several times a day, to be an effectual remedy in migraine.

Reseda (Mignonette): a Vermifuge (*Journal de Médecine de Paris*, February 5th, 1888).—This plant appears to have a great reputation in Russia for the expulsion of tapeworm. A strong decoction of the dried flowers was taken on an empty stomach by a woman suffering from the presence of a *tœnia*. This was followed by a full dose of castor oil; the worm was expelled three hours afterwards.

Dangers attending the Use of Coloured Chalks. By Professor Jungfleisch (*Fortschritt.*, January 5th, 1888).—The drawing-boards are used in many schools for illustrations with coloured chalks which may prove dangerous. These drawings being rubbed off by a dry sponge are a source of danger from the chalks which are coloured with preparations of litharge, chromes, quicksilver, etc. Professor Jungfleisch points out that other and innocuous colouring materials might be employed.

Lactic Acid in Diarrhoea Neonatorum (*Der Fortschritt. Genf.*, February 5th, 1888).—M. Hayem points out that the dose usually given is too small; that from fifteen to twenty teaspoonfuls of a two per cent. solution should be given in the twenty-four hours. He recommends this remedy for obstinate diarrhoea of adults also.

The Hypodermic Injection of Quinine (*Journal de Médecine de Paris*, February 5th, 1888, from *Vratch de St. Petersburg*).—The hypodermic and intra-muscular injection of hydrochlorate of quinine is reported from Russia to be a sovereign remedy in marsh fever. One part of the salt is dissolved in two parts of water; by the aid of heat a portion, containing fifteen centigrammes, of the salt is taken up in a Pravaz syringe, the needle of which is plunged perpendicularly into the glutæi. The injection, it is stated, produces no irritation or induration of the tissues.

The Distribution of Non-Striated Muscular Fibres in the Muscular Coat of the Small Intestines. By Kultschitzky (*Fortschritt. der Medicin*, Berlin, February, 1888).—According to the author, the muscular fibres are inserted immediately beneath the epithelium, and near the Lieberkuhn's glands, and pass in the long direction of those glands without definite relation to the lacteals of the villi. Some fibres also run parallel to the axis of the villi, and by their contraction effect shortening thereof. The curved direction of the fibres dilates the central canal, thereby facilitating the outflow of the chyle. Striated muscular fibres are not met with in the villi.

Illustrations of the Histologic Changes of the Nervous System in Leprosy. By John C. Shaw, M.D., Brooklyn (*Brooklyn Medical Journal*, January, 1888).—The author of this paper quotes opinions from many authorities upon the pathology and etiology of leprosy, and observes that the theory of contagion is rapidly spreading, and urges the isolation of patients suffering under this disease. An examination of the central and peripheral nervous system, in one case, showed us marked changes in the spinal cord. The peripheral nerves showed an amount of induration in marked contrast with normal nerves. Interstitial and perineuritis were found everywhere. The connective tissue of the nerve bundles was dense. There was a remarkable absence of fat among these. Few nerve-tubes were left; it was almost impossible to find a trace of myeline. Here and there a solitary axis cylinder could be found, devoid of myeline covering. Around the nerves there was a large increase in the number of nuclei of connective tissue. A mass of lepra cells was to be seen in the centre of the nerve bundle, in one instance that was examined. A small nerve bundle was found to be filled with a large number of irregular-shaped bodies, the nuclei of which were sharply stained with logwood. Numerous cavities and vacuoles were to be seen in these bodies—the so-called lepra cells of Virchow. The bacilli of lepra were seen in abundance. The disturbances of sensibility are due to neuritis and perineuritis of the peripheral nerves. Daniellson and Bock describe sclerosis of the cord with atrophy of cells. Langhaus has discovered softening of the posterior horns and of Clark's column, in the cervical and dorsal regions. Other pathologists have also described these pathological changes.

Chloride of Methyl, a Local Anæsthetic (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, February 5th, 1888).—M. Duboué has extolled the effects of chloride of methyl in neuralgia, especially also in sciatica, and has employed it as a local anæsthetic. M. Bailly, of Chambly (Oise), has modified and carried to perfection the mode of application of this remedy, and has submitted his modifications to the Academy of Medicine, upon which M. Vidal has drawn up a report in the *Comptes-rendus*, in the *Bulletin Medical*. The report shows the modes of local application of this local anæsthetic in neuralgia. M. Bailly has simplified the method of its use, so that instead of its employment in a gaseous form, he has by means of a

specially contrived apparatus—a form of tampon or pledget—been able strictly to localise its action, and restrict it to a limited point. The application continued for a few seconds produces a sensation of cold, which is followed by a reaction; if continued further, sensibility is blunted, the part become of a pale tint, and reaction occurs with a sense of itching; persevered in beyond this stage, phlyctenæ and eschars may be formed. The liquid chloride of methyl requires a special apparatus, which M. Bailly designates *le stype*, and its employment *stypage*. M. Bailly reports cures in twenty-six cases of dental neuralgia, eight cases of sciatica, sixty-two of various forms of neuralgia, and numerous cases of lumbago, and in visceral pains of various character. The application of chloride of methyl has also been reported to have been found of signal service in some minor surgical operations. M. Berniers has employed stypage in the treatment of affections of the mucous membrane of the vulva, etc., the parts being previously covered with gold-beater's skin, which prevents the production of eschars. The sensation of cold from the chloride of methyl is as intense as that from ether.

A Coincidence of Human and Poultry Diphtheria (*L'Union Médicale*, February 14th, 1888).—M. Menzies has traced an outbreak of diphtheria in Naples to the pollution of drinking water by the dung of pigeons, the water from the roofs of the pigeon houses finding its way to the source of the drinking water. M. Menzies states that of a population of 4,000 individuals, 125 were attacked, of whom thirty-six died. This occurred in 1884 at Skiotos, an island at the north of Greece. It was found that diseased turkeys had been introduced into the island. Among these birds a form of disease resembling human diphtheria had been developed. The virus, he states, was conveyed by the air to human beings, and gave rise to the epidemic.

On the Influence of Lanoline upon Micro-Organisms. By Dr. A. Gottstein, Berlin (*Der Fortschritt.*, January 5th, 1888).—The author, by a series of experiments, states that he has established the fact that lanoline presents the development of microscopic germs. This result has both therapeutic and biological interest. Liebreich has shown that the cholesterine, which enters into the composition of the integuments of animals, presents a chemical composition similar to that of lanoline. Like the latter it prevents their decomposition, and the passage of micro-organisms; and thus provides human and animal bodies a protective covering from organic germs.

Action of Fluid Extract of Quebracho as an External Application. By M. Bordeaux, Geneva (*Der Fortschritt.*, January 5th, 1888).—Quebracho, the author has found to be a useful means of securing cicatrisation, painted over a clean smooth wound it excites a passing and smarting pain, like that of collodion, and promotes healing by the first intention. It is equally serviceable for burns and frost-bites. Painted on the surface the extract hardens in about an hour, and forms a brown crust, which adheres firmly to the tissues, but can readily be removed by warm water. If left to dry on, it will, after a time, fall off, leaving the wound healed. Other dressing is not required.

[Quebracho bark, from the *Aspidosperma quebracho*, is imported from the Argentine Republic, in pieces of about three-quarters of an inch thick, with a fibrous cinnamon-coloured interior. It has a bitter, slightly aromatic taste. It contains six alkaloids.—*Extra Pharmacopœia*, 1885, p. 295.]

Terchloride of Iodine as an Antiseptic and Disinfectant. By Langenbech (*Centralblatt für Chirurgie*, February 4th, 1888).—The terchloride of iodine is a volatile, orange coloured powder, with a pungent odour, and requiring to be kept in a closed glass tube. Dissolved in water it forms a mahogany coloured solution, which must be protected from the action of light, as this converts it into a monochloride, which, however, has also antiseptic power. These changes in solution are rapidly effected on coming in contact with organic matter. The chlorine and iodine are liberated in a nascent state. For surgical purposes the author employs a solution of 1 in 1,000, to 1,500, a degree of concentration which is about equal to a four per cent. solution of carbolic acid, or half to one per cent. of sublimate solution. Riedel states that the destroying influence of the terchloride over spores is next in usefulness to sublimate. The solution is useful for disinfecting the hands of an operator, the sponges, instruments, etc. Applied on gauze or lint it forms a dressing for wounds.

Laparotomy in Extra-Uterine Pregnancy. By Geo. R. Fowler, M.D., Brooklyn (*Brooklyn Medical Journal*, January, 1888).—The patient in this case was suffering from an abdominal tumour, and symptoms of septicæmia. She stated that she noticed enlargement of the abdomen about a year and a half before she had consulted a physician. No clear history could be obtained as to disturbance of the menstrual function at that time, but she asserted that they had latterly been "quite regular." An ovarian suppurating tumour was suspected, and

an operation was determined upon. Laparotomy was performed, and upon the first incision made, the head and limbs of a seven months' foetus were clearly discerned through the thin envelope. This being punctured, gave exit to about half a gallon of "most horribly offensive fluid and debris." A hot solution of hydro-naphthol was poured into the abdomen, and the contents of the sac were turned out. A drainage-tube was placed at the lower angle of the wound, and the patient placed on her side to favour the draining away of the hydro-naphthol solution. Nothing untoward occurred in the after history of the case. In a month after the operation she was "out shopping."

Bright's Disease (Large White Kidney) : its origin in Poisons engendered within the System. By M. Gaucher (*L'Union Médicale*, January 17th, 1888).—M. Gaucher reviews the pathological opinions which regard the large white kidney as a chronic epithelial nephritis, and recognises a different pathological source—toxic—originating insidiously in a poison produced within the organism itself. This poison is of a complex nature, consisting of extractive matters, which are the results of the imperfect oxidation of nitrogenous substances. From his experiments, M. Gaucher considers that he has proved the noxious action on the kidney of these poisonous matters. By the daily subcutaneous injection into guinea pigs of a watery solution of creatine, leucine, or tyrosine, the urine of the animal was rendered albuminous. The animals finally die, and on *post-mortem* examination the kidneys presented all the characteristics of "white kidney." Thus it appears that the accumulation of extractive materials in the blood may irritate the secreting epithelium, and give rise to a parenchymatous nephritis. All these extractive materials exist normally in the blood in minute quantities, but are greatly augmented in pathological conditions. In the first place, disorders of the liver hinder the transformation of nitrogenous matters, at the same time that the excretion of the urine is diminished. Thus it is that albuminuria frequently accompanies jaundice and diseases of the liver. In all chronic diseases the elimination of nitrogenous matter is interfered with, and a toxic influence exerted upon the kidneys. It is not only in disease that the extractives exercise a modifying action upon these organs. Articles of food containing imperfectly oxidised nitrogenous substances, such as meat extracts, bouillon, etc., retard elimination. Thus the administration of these articles of diet in cases of nephritis is contra-indicated. In Bright's disease, M. Gaucher considers bouillon as a poison. Even in health these preparations of meat may exert an injurious influence, but it follows that in chronic disease a double danger is incurred by the accumulation in the system of such toxic materials through their defective elimination.

On the Diuretic Action of Caffeine and Allied Substances. By W. von Schroeder (*Fortschritte der Medicin*, January 15th, 1888).—V. Schroeder has previously shown that caffeine acts directly upon the renal epithelium, at the same time that a contraction of the vessels is occasioned by this agent. Caffeine, it is known, causes not only a general reflex spasm of the vessels, but also by increased action in the central vaso-motor apparatus, a spasmodic tension of the vessels, leading to augmented blood-pressure. Division of the vaso-motor nerves of the kidneys, or narcotism of the nervous centres, allows the action pure and simple of caffeine upon the renal epithelium. The author had used chloral, but now employs paraldehyde for the narcotising of the nervous centres. This substance, administered alone to rabbits, increases the quantity of urine to the amount of one per cent. of the weight of the body; when given with caffeine, the diuresis is raised to from three to five per cent. of the same weight. The relative proportion of solid material is at the same time increased from fourteen to fifteen per cent. The mass of blood in a rabbit being estimated at from 100 to 150 grammes, this would imply a loss in the blood of from one to two grammes of water, the quantity of urine being augmented from 100 to 130 grammes. Caffeine has no similar diuretic action in dogs, a noteworthy fact, which remains to be accounted for.

Hemiatrophy of the Tongue : State of Nerve-Roots (*Fortschritte der Medicin*, March 1st, 1888).—M. M. Marie and Koch had recently an opportunity of examining the hemiatrophied tongue, in a case of tabes. The hypoglossæ on the atrophied side were notably degenerated. The multipolar cells were few in number, and but few nerve-fibres were given off. The cells of the accessory hypoglossal nucleus were wasted away. It was interesting to find that fibres passing from the raphe to the nuclei were not all atrophied.

Ganglions in the Palm of the Hand, as a cause of Neuralgia. By Dr. O. Witzel, Bonn (*Centralblatt für Chirurgie*, February 25th, 1888).—The author relates cases of ganglion cysts, which had been the cause of severe neuralgic pains, extending up the entire upper extremity from the palm of the hand and flexor tendons to the shoulder. The use of the limb was in some cases destroyed, and cure only effected by the removal of the cyst.

II.—NOTES FROM RUSSIAN JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

Permanganate of Potash as an Emmenagogue.—In the *Meditzinskoi Obozrenië*, No. 19, 1887, p. 581, Professor Ivan M. Lvoff, of Kazan, publishes a valuable clinical paper on the use of permanganate of potash as an emmenagogue. The paper is based on as many as 187 consecutive cases of amenorrhœa and dysmenorrhœa, which the author has met since the appearance of Drs. Sydney Ringer's and W. Murrell's communication in the *Lancet* (June 6th, 1883), and in all of which he invariably employed the drug recommended by these two eminent physicians, whose names and works are scarcely less familiar with the Russian profession than with the British one. The formula used by Dr. Lvoff was always this: $\text{R Potassæ hypermanganicæ, Extracti pulsatillæ sicca ana, 4.0; Vaseline q. s. ut f. pil. No. 60. D. S. To take two pills three times daily.}$ The author divides his rich clinical material into five distinct groups.

The first of them includes thirty cases, referring to more or less *anæmic girls* (virgins), who came to him with complaints to the effect that "their menstruation had of late, without any apparent cause, become gradually more and more scanty, and associated with ever-increasing agonising pain." In many of them, "catamenia, which had been formerly profuse, and of five or seven days' duration, of late lasted some two or three days, and well-nigh left no traces on the patient's linen," while their dysmenorrhœic pain "became unbearable and incessant." The permanganate pills were given daily for seven or ten days before, as well as during, the menstrual period. A similar course was repeated three or four successive times. The treatment was crowned with a uniformly striking success in every one of the cases. In all the patients, already the first menses were by far more profuse and almost painless, while those following a second or third course of the drug proved quite normal in all regards, and remained such thenceforward, without any further use of the permanganate. Neither the duration of the menstrual disorder before the treatment, nor the patient's age, seemed to manifest any influence on the therapeutic result in this group of the cases.

The second category consists of seventeen cases of *absolute amenorrhœa* in women, aged from twenty to forty, "with a hyper-involution of the womb after their last labour, or with atrophy of the uterus and ovaries, which supervened after a prolonged puerperal parametritis, or some other pelvic inflammation." The patients—some of whom were looking rather anæmic, while others were apparently enjoying a flourishing general health—always stated that their last puerperal period had been irregular, and that no catamenia had come since their last delivery, amenorrhœa lasting in some of them as long as two years. All of them complained of headache, cerebral congestion, ear-noises, giddiness, etc. The pills were administered here regularly daily for the period, varying from three to six months. In young and comparatively strong women, menstruation was re-established in about four or six weeks, to recur in due terms ever since. But in rather weak women, aged from thirty-five to forty, menses made their appearance only after the permanganate course of from three to four months' duration, while a due regularity in their subsequent recurrence was regained but gradually (in several months). As regards the nervous symptoms mentioned above, they always disappeared tracelessly in the very beginning of the treatment.

A third group embraces sixty-two cases where, as previously, normal menstruation in formerly healthy women became irregular, scanty, and associated with intense spasmodic pain after the patient had gone through an attack of *puerperal* (or also non-puerperal) *pelvic peritonitis*, but where a careful gynecological examination failed to detect any serious anatomic changes in the womb and ovaries, beyond a slight enlargement or induration of the organs, or cervical cyanosis, uterine catarrh, etc. The drug was given daily for ten days before the expected menses. On the whole, the results were satisfactory also in this category of the cases. In certain patients, however, the permanganate either failed altogether, or brought about but a partial improvement lasting only during the use of the pills. Such less successful results were obtained (a) in cases of dysmenorrhœa of long standing, and (b) in the presence of "a small or also normally-sized womb, with dense walls abounding in connective tissue," as well as in the presence of dense peri-uterine adhesions.

A fourth group is that of sixty-five married, but childless, extremely nervous and hysterical, mostly young women, suffering from amenorrhœa, or dysmenorrhœa with scanty menstrual discharge. All of them were strongly exhausted by some severe acute disease of their genital organs, which had developed during the very first days of the married life, the symptoms being the whittings, irritation about the genitals, extremely frequent and painful micturition, dyspareunia, and menorrhagia. Having examined the vaginal discharge in many cases of the

kind, Dr. Lvoff found Neisser's gonococci in everyone of them. Nearly in a moiety of the patients there were present adhesions of the womb, ovaries, and Fallopian tubes, painful dilatation and distortion of the latter, painful enlargement of the ovaries, chronic metritis, with a scanty muco-purulent discharge, etc. The permanganate gave good and durable results only in a very small number of such cases where no marked morbid lesions about the internal genital organs could be detected. In the remaining patients the drug proved entirely useless, even after a prolonged persistent administration.

The fifth and last group consists of eleven cases of a *premature climacterium* in women, aged from thirty-five to forty, with atrophy of the womb. Permanganate of potash here remained utterly powerless to effect anything beyond removing headache, flushings, cardiac palpitation, and such-like symptoms. Not a single instance of any unpleasant accessory effects of the drug was observed by Professor Lvoff.

It is not difficult to foresee of what nature the author's general corollary might be. Dr. Lvoff thinks that S. Ringer-Murrell's remedy is not only an extremely useful, but simply an indispensable therapeutic acquisition for the gynecological practice. In fact, as far as the first group is concerned, "there does not yet exist any better and more reliable means than permanganate of potash." Nearly the same may be stated in regard to the second category of the cases, which are cured by the drug as surely and as permanently as the preceding group, though sometimes rather slowly.—[Drs. Korotkevitch's and Gerditchevskaja-Tchernobaiëva's recent communications on the subject may be found in the *Provincial Medical Journal*, December 1st, 1887, p. 566.—Reporter.]

Cocaine as a Local Anæsthetic in Reduction of Luxations.—In the *Médecinskoïé Obozrenië*, No. 19, 1887, p. 604, Dr. N. I. Grigorieff, of Myshkin, the Jaroslav Government, briefly details five cases of various luxations (viz., two of sub-glenoidal dislocation of the right humerus in a man of forty, and a woman of sixty; two of luxation of the radius and ulna in the left elbow-joint in women, aged fifty-three; and a case of displacement of the left thumb towards the palm in a boy of thirteen), in which he resorted to cocaine for making their reduction painless. He used a 5 per cent. solution of the hydrochlorate, injecting half a syringeful at three or four points in the neighbourhood of the injured joint (the total amount being, therefore, from one and a half to two syringe-fuls). In about three or five minutes a complete anæsthesia of the parts and relaxation of the adjacent muscles took place. The reduction was quite painless, and could be effected in a "jiffey," the patient manipulated upon, never uttering a sound or moving a limb. The patients were peasants and, as is invariably the case with Russian rustic people, came to the hospital only after they had gone through, and nearly mad from, an obligatory ordeal in the shape of a long series of unsuccessful attempts at reduction, performed by friends and neighbours, young and old, "wise men" and "wise women." The patients' surprise in regard to magical painlessness and rapid effectiveness of a "genuine doctor's" bone-setting manipulations was as intense as agreeable.

III.—EXTRACTS FROM SPANISH AND OTHER MEDICAL JOURNALS.

TRANSLATED BY DR. G. CADOGAN-MASTERMAN.

Carta. . . . acerca du un asesinato que quedó oculto (*Revista de Ciencias Médicas de Barcelona*).—There is an old story of a Highland drover being found dead in the bedroom of a village ale-house, with no sign of external injury but a small puncture at the back of the neck. His companion, who was charged with murdering him, was able to prove that he possessed no lethal weapon, no sound of quarrelling or struggle had been heard; therefore, with some demur, the theory of the defence was accepted, that the man had fallen backwards when helplessly drunk on to a projecting nail on the floor (which was pointed out), and which had passed through the nape of the neck, and so killed him. On his death-bed, however, some years afterwards, the prisoner confessed that he had really murdered the man as he lay in drunken stupor on the bed, by thrusting in the point of a pair of iron snuffers at the spot where the wound was found, afterwards laying the body, with emptied pockets, supine on the floor. And there is, also, a gruesome legend of sundry decrepit hags, and who used, for a consideration, to despatch newly-born infants whose existence was objectionable, by pushing a darning needle into the medulla, through the same perilous interspace between the atlas and the axis, leaving nothing but a bloodless and almost microscopic puncture as the sole outward evidence of the murderous outrage. In Spain there is no equivalent to our generally farcical, but occasionally useful, coroner's jury, the doctor—usually with us the decisive witness—there reports directly to the nearest magistrate, and he, if satisfied, issues the order for the interment or otherwise, in all cases where there may have been

any doubt as to the cause of death. Now, this duty—the verification—may be performed ignorantly or perfunctorily, the body cursorily examined, and mere gossip and inference accepted as trustworthy evidence, and, as an example, the following narrative is given by Don Francisco Ximeno:—A young man, of more than doubtful reputation, was working for a dyer, who lived in an isolated house some little distance from Barcelona, and had contracted improper relations with his sister Marieta. They, in company with another workman as bad as themselves, were engaged in a drinking bout one afternoon on their master's birthday. The latter was generally abstemious, but on this occasion he drank the better part of a bottle of gin, which made him very sick, and he laid himself down on a bed, and fell into a drunken sleep. After a time his breathing became so irregular and stertorous, that Marieta, in alarm, set off to the city to get some medicine. After she had gone, one of the men looked into the bedroom, and said contemptuously to his companion, "See how that sot is sleeping! but I'll soon wake him up." And stepping softly into the workshop, came back with a carpenter's brace and a slender drill in his hand, drew his master's head, with the face downwards, over the side of the bed, and leant over him. There was a quick turn or two of the brace, a piercing scream, a long shuddering spasm, and the man was as dead as a door nail. The two miscreants were at first petrified at the result, then one proposed robbing the house and decamping; but, after a quarrel, they agreed that it would be safer to remain; so they withdrew the drill, wiped away a spot of blood from the scarcely visible wound, laid the corpse on its back, and sat down quietly in the next room until the girl returned. Then pretending to be concerned at their master's long sleep, they advised that a doctor should be sent for. He, on his arrival, found the man, of course, dead; but, from the account Marieta gave in perfect good faith of the gin drinking, the vomiting and stertor, and the well-acted astonishment of the men, all suspicion was averted, and a *procès verbal* was drawn up, in the presence of a second acquiescent doctor, who, like his *confrère*, never thought of looking for a needle-prick at the back of the neck, to the effect that the man had died from alcoholic apoplexy, and he was duly buried. Shortly afterwards, however, Marieta overheard her paramour quarrelling with his confederate over the hush money, and the next day he was found murdered at the back of the house. The criminal disappeared, but apprehended afterwards for coining, was shot in attempting to escape from the hulks, and told the whole ghastly story before expiring. The moral is: In cases of theoretical apoplexy, especially in those called "serous," and in which the excess of serum often exists but in the imagination of the autopsist—carefully examine the *medulla oblongata*.

On the Modern Treatment of Fever. By Dr. Unverricht, Jena (*Ciencias Médicas de Barcelona*).—The history of the theory and treatment of fever in any given epoch, may be said to be for that time the history of medicine itself; opinions and hypotheses of the most contradictory character appearing, flourishing and effacing, only to be in their turn displaced and forgotten, but perhaps resuscitated, from the dust of ages to be once more reburied in completer oblivion. For nearly a quarter of a century the views of Liebermeister have been paramount—that fever is simply an excessive development of the natural heat of the body; the phenomena of accelerated pulse and respiration, and the sensory and muscular perturbation being no more than the direct consequences of this abnormal incalcescence. And, as a corollary, that its treatment resolved itself into the discovery of means for reducing rapidly or slowly the body to its ordinary temperature, when all the dangers attending the disease should simultaneously disappear also. It is interesting to note how this theory having been built upon false (badly interpreted) observations led to the *past hoc* being confounded with the *propter hoc*. It was seen that patients suffering from typhus did better with the cold-bath treatment than under an older system, and as cold water necessarily lowered the surface temperature, this got the whole credit of an improvement really due to the disuse of other remedies, and to the inference that cold would be equally useful in the treatment of every other febrile condition. And when, too, the fallacious system of taking the temperature in the axilla only was trusted implicitly, many talked of the cooling of the whole body when it had really been one of purely surface refrigeration. At the present day few can be found who believe that the entire efficacy of hydrotherapy is due to a mere lowering in temperature, inasmuch as it cannot compete in that way with internal antipyretics of the most modest pretensions. From the statistics of Liebermeister himself, founded on more than 6,000 observations, it is shown that the effect of an immersion in a bath of 20° for fifteen minutes, only led to a fall of 0.46° in males, and 0.35° in females; therefore, the more one is convinced of the necessity for reducing the heat in febrile cases, the more urgent is the need to find agents which can effect it with greater speed and certainty than cold water. "In the pursuit of this idea we are arrested by the glorious name of Lister, for he showed that the most effective

antiseptics are antipyretics also;" and, as carbolic acid was one of the first to be employed by him, the whole of the aromatic series was examined by chemists, and especially the derivatives of benzol in search of it. And in this way synthetic salicylic acid was formed by the combination of phenic and carbonic acids, a discovery which was received with that generous enthusiasm which welcomes every new remedy, and it was soon employed in the treatment of all forms of pyretic disease. Riess, the most fervid supporter of the idea, gave it in his typhoid cases whenever the temperature exceeded 102 degrees, and had the triumph of recording that many passed through the disease with scarcely any elevation of temperature at all; it is true that 26 per cent. died, but that accident did not, of course, invalidate the accuracy of the theory, nor deter him from using other remedies of the same class in similar heroic fashion. He successfully supported his thesis that the rôle of antipyretics is the reduction of temperature, and after all *ἡ ἀρὰ τοῦ πυρετοῦ!*

When the novelty had worn off, there were so many unfavourable reports as to the action of salicylic acid, that it was clear that its admirable effects in acute rheumatism were no evidence of its worth in treating other febrile affections. The induced restlessness, the singing in the ears, the profuse perspiration, and occasional occurrence of collapse, showed the danger of employing it too freely; and the more serious effect was observed that the falling temperature was accompanied by an accelerated pulse, an indication of cardiac failure which excited the gravest apprehension, for, in diseases of long duration, all depends upon the heart power and integrity.

With renewed hope three isomeric dihydroxibenzoles were studied in search of a refrigerant free from these defects, *resorcin*, *hydro-quinina*, and *catequina*; the first, however, was alone available, the two latter being too poisonous for internal use. And resorcin itself was not free from danger. Lichtheim observed amongst his patients, shortly after taking it, vertigo, noises in the ears, suffusion of the face, hurried respiration, with accelerated and intermittent pulse. Then, in about ten or fifteen minutes, a rapid fall in temperature—but with an equally rapid rise to a still higher point a few hours afterwards—the urine became blackened and albuminous, and cerebral disturbance was initiated or exacerbated. It was evident that the lowered temperature was purchased too dearly. Then another group, derived from the decomposition and rebuilding of the molecule of quinine, was examined. *Quinolina* failed utterly, and, although Gerhardt believed it was a specific in diphtheria, is well-nigh forgotten. But *cairina* has been more successful, it will reduce the temperature in any case, but only temporarily, the next day it will be—unless the remedy be repeated—as high as ever; and Guthmann, who praised it enthusiastically, admits that the course and duration of the disease were not in the least affected by it. And with this agent, as before, we find Riess apparently determined to test the utmost endurance of the human organism; for, not satisfied with giving from .5 to 1 gramme every hour, whenever the temperature of his patient exceeded 100° to 102°, even when this necessitated twenty doses in twenty-four hours, he reached at last the enormous dose of 3.5 grammes, and then only withheld its repetition on the appearance of persistent cyanosis, stupor and a pulse of thirty-six per minute. He thought nothing of rigors lasting for more than an hour, of profuse sweating all day, of albuminuria, and that the pulse, when the lowest degree was reached, was often over 100 per minute, and he mentions, with satisfaction, that his delirious patients (to their great credit) exhibited marked "euphoria, manifesting itself sometimes in hallucinations!" Schulz, of Brunswick, was at first alarmed by its coincident effects, the profuse diaphoresis, the state of collapse, the terrible rigors "which shook the bedstead," nevertheless he used it in twenty-one cases, expending 1,017.25 grammes of *cairina*, at a cost of 305 marks (about £17 15s.) What with the profuse sweating, the rigors, epistaxis, collapse, urticaria, vomiting and general misery, the patients, not unnaturally, rather preferred the fever to the remedy. And as relapses occurred in 40 per cent. of the cases, Schulz asks if they were not really due to the action of the *cairina* itself, and very pertinently observes, "does not this induce us to believe in the teleological importance of fever? Supposing that enteric fever is due to a typhoidal bacillus, which an elevated temperature gradually destroys, may we not believe that its reduction, by the use of *cairina*, really favours the vitality and reproduction of the bacilli, and that we are thus arresting the course of a natural remedy, and not only prolonging the disease, but inviting a relapse?"

After Müller had observed, in several cases, coma with incontinence of urine, and other observers had recorded similar evil effects, it was inevitable that this medicine, from which so much had been anticipated, should fall into deserved oblivion. It was succeeded by *talina*, the undoubted antipyretic powers of which were tested on a large scale by Jacksch in the clinic of Nothnagel. In doses of .25 to .75 gramme there was the familiar temporary fall in temperature, with profuse

sweating and rigors, but neither vomiting, cyanosis nor collapse, so it was a decided improvement on the last. *But the course and duration of the attack were not modified in the slightest degree.* In spite of this not inconsiderable defect, yet another was brought into the market, and one which may be called the crowning triumph of the antipyretics—*antipyrina*. Filehne, who was the first to try it, observed, that administered in quantities of five or six grammes, in divided doses, within three hours, the temperature fell to the normal point in from seven to nine hours, that the apyrexia often lasted for twenty hours afterwards, and that the temperature then rose gradually without rigors. Also, that the descent was gradual, without much diaphoresis, and with no collapse, only the pulse did not fall correspondingly. And although some disagreeable effects were not long in showing themselves—urticaria, giddiness, and gastric disturbance—it is evident that we have here an agent which equitively satisfies those who believe that the sole point in the treatment of fever is cooling it. But, alas, the more perfectly the postulates of the apyrexiaists are satisfied, the less satisfactory are the curative results—the patients are effectually cooled, but they are not one whit the better for it; the disease pursues exactly the same course, notwithstanding the refrigeration. Schulz had 40 per cent. of relapses, Eichhorst saw that the worst symptoms persisted under the system, and Freimuth and Poelchen traced the luxuriant growth of spirilli in the blood, in spite of it. Then, is not this question apt to present itself to the impartial observer: If this be the sole result of the modern treatment of fever, have we really gained anything in adopting it?

That a high temperature is necessarily fatal or perilous remains to be proved; it is extremely unlikely that the limits of safety are so narrow above the normal point, when we know that a fall of 10° or 12° is compatible with survival below it, and the more exact clinical observations show that most patients do not die from overheating, but from other causes; it is not the fever but its complications which put an end to existence. Volkmann and others have pointed out that the most fatal diseases may exist with a low temperature—peritonitis, for example—and, on the other hand, that there may be high thermometric readings and no danger.¹ After aseptic operations his patients were feeling quite well, laughing, joking, playing at cards, and eating prodigiously, and it was only by chance that he noted that the axillary reading was often 104°. And, *vice versa*, in the campaign of 1870 Fräntzel saw severe epidemics of typhus, with every pathognomonic symptom, rapid pulse, frightful prostration, furious delirium, and a mortality of 39 per cent., and yet with low temperatures. And in enteric cases Wernich observed that those with the worst results, and especially with brain complications had the least fever. From all this it is evident that the danger of elevated temperature is far from being proved, and that even the old opinion that it was salutary can scarcely be dismissed, now that we know that it is inimical to microbic existence, without more consideration than it has lately received. Naunyn has shown, in an extended series of experiments, that rabbits can endure for weeks together a temperature of 106.2°, with occasional rises to 107.6°, and even to 109.4°, and there is really nothing to *prove*, he says, that the mere heat is dangerous to the human system, but that the heretical dogma might rather be sustained, that fever is, in the face of microbic intoxication, a somewhat beneficent institution for the human race. For the recent observations of Pipping have demonstrated that, although bacilli are not killed by the temperature of pneumonia, that they then at least cease to multiply and flourish (*Deutsche Med. Wochenschrift*, No. 21).

IV.—INTERNATIONAL MEDICAL CONGRESS.

GYNÆCOLOGICAL AND OBSTETRICAL NOTES.

(Communicated.)

(Continued from page 131, March, 1888).

PROFESSOR SIMPSON, Edinburgh, was very prominent, and we fully appreciated the valuable aid he rendered in the section. His method of Obstetrical Nomenclature was favourably received, and I hope it will be permanently and generally adopted. The papers read at the Congress in the sections above mentioned were well sustained even to the last day of meeting, and included the following. From the *Medical Record*, New York, I give you some extracts:

Treatment of Puerperal Eclampsia.—Dr. Ira Oatman (San Francisco) treated this subject. When convulsions occurred before labour he recommended anæsthesia, clearance of the bowels and rectum, together with as rapid delivery as was compatible with the safety of the patient.

¹ I have lately been treating two cases of simple fever, in adolescents, with a temperature of 104—5°, for days together, without any apparent mischief and little distress.—*Trans.*

When the convulsions occurred after delivery, and were accompanied by high, nervous, and vascular tension, nothing was so safe, speedy, and reliable as veratrum viride, in doses of ℥vi. by the mouth, or ℥x. by the rectum, every fifteen minutes, until convulsions ceased.

Should the veratrum cause excessive depression an immediate and certain antidote was found in alcohol. It was better to give the veratrum in excessive doses than to risk the continuance of the convulsions, for brandy or whisky to counteract its effect were always present, and the veratrum certainly exhibited a remedial action not otherwise attainable. The puerperal period was to be treated as usual, together with treatment of any pathological condition present. He found the veratrum equally efficient in the convulsions of children and in hystero-epilepsy.

Dr. Alexander Simpson, of Edinburgh, Scotland, thought any suggestion that would enable us to control eclampsia of extreme value. He would like to hear opinions regarding veratrum; he had used it once twenty years ago, and had not felt inclined to try it again.

Dr. G. Lane Taneyhill, of Baltimore, Md., advocated strongly the use of veratria in eclampsia, and said that fifty per cent. of his cases had, in the last twenty years, been treated by it, he giving ten drops of the tincture, hypodermatically, every hour of convulsive action, and always keeping another hypodermic syringe with brandy to sustain the heart should the pulse go below forty-two. He was led to this practice by observing its use by Latimer in a case which he could control but temporarily by chloroform. He had not lost one case of eclampsia since using veratria; it enabled him to hold the engine (the heart) in check as an engineer with the air-brake, and was not as dangerous a medicine as was generally supposed. It produced the same effect as bleeding, save that no blood was lost to weaken the patient afterwards.

Dr. Duncan C. MacCallum, of Montreal, Canada, had fourteen cases; all recovered. He used chloral, chloroform, potassium bromide, bleeding, morphia hypodermatically, and cleaned out the bowels by stimulating enemata. There was no routine treatment; each case was to be treated on its own merits.

Dr. Pierce, of Ohio, thought it foolish to try to map out any one line of treatment for eclampsia; each case must be rationally treated.

Dr. Lawrence, of Bristol, England, believed in as early delivery as possible, and the use of chloral. In plethora, bleeding was sometimes useful. It was difficult to lay down definite treatment.

Dr. Jones, of Danville, Ill., said that veratrum was an active purgative, and a loaded colon was an active agent in causing epileptiform convulsions. He took charge of his patients beforehand, kept their bowels regular, used chloroform in labour when any nervous symptoms appeared, and saw no cases of eclampsia.

Dr. A. F. A. King, of Washington, D. C., had never used veratria in eclampsia, but had suggested its use twenty years ago theoretically (*New York Medical Journal*, October, 1865), to lessen arterial hyperæmia of the nerve-centres, by reducing the force of the heart. He then, and more recently (in the *American Journal of Obstetrics*, March and April, 1887), considered, and still considers, eclampsia to be caused chiefly (and in addition to uræmic poisoning) by abnormal pressure of the gravid wound upon the aorta and its branches, and vena cava and its branches. He believes this abnormal pressure to be chiefly due to premature descent of the lower uterine segment and foetal head below the brim into the pelvic cavity, especially in primiparæ, two or three months before full term. In transverse presentations, whether in multiparæ or primiparæ, eclampsia does not occur. The head of the child ought not to sink below the pelvic brim before labour—in fact, such descent is the second stage in the mechanism of labour. Yet recent authorities affirm that it is usual, and therefore normal, in primiparæ. This he denied. He maintained that the normal posture of the fetus during pregnancy, before labour begins, is transverse or oblique; a head-presentation is abnormal until the sinking of the womb just before delivery, when it changes in order that labour may take place. To remove the cause of and prevent eclampsia, we should, by posture and manipulation, lift the prematurely descended head out of the pelvis, and put it above the brim in one of the iliac fossiæ, where it normally belongs, and where it would have remained but for corsets, dress, coitus, and other displacing influences.

Dr. W. W. Jaggard, of Chicago, Ill., said: 1. Eclampsia is a symptom of renal insufficiency, renal inadequacy, to use a term of Sir Andrew Clarke's, the result of functional or organic disease. The arguments of Dr. A. F. A. King were entirely inconclusive. 2. The cause of the convulsions were cerebral anæmia, the result of vaso-motor spasm, caused by irritation of the vaso-motor centre, by excrementitious matter retained in the blood. 3. The indication for treatment was absolute continued narcosis. He used chloroform, potassium bromide, chloral, morphine. Veratrum viride, according to the researches of Wood and Behrens, of Philadelphia, causes vaso-motor dilatation, and the woman is literally "bled into her own veins." Pilocarpin is unreliable, causing cardiac depression, and aiding in œdema pulmonum when

no diaphoretic action is effected. Professor Fordyce Barker has frequently called attention to this fact.

Dr. Oatman said that he had seen large doses of as much as a drachm of the fluid extract of veratrum taken by mistake and recovered from without treatment.

Dr. H. O. Marcy, of Boston, Mass., read an elaborate paper on the **Histology and Pathology of Reproduction**.—The studies offered were based upon the conviction that the profession owes to the late Professor Ercolari, of Bologna, the establishment of new and simple truths which are fundamental and of the first importance. Comparative studies teach that there is a unity of type in placental development. The writer endeavoured to show that immediately after conception a destructive process affects the inner surface of the uterus; in some animals and in women this process is limited to the epithelium, while in other animals, as in the rodents, the destruction extends to the entire submucous connective-tissue layer. This destruction is essential, since it facilitates the setting up of neo-formative changes, from which will result the maternal portion of the placenta. This process consists in the formation of new vessels, which are distinguished from the vessels of the unimpregnated uterus in that both the artery and vein consist of only a simple endothelial wall, and that from the external surface of this is elaborated a layer of special cells not separable from the wall of the vessels. These are the so-called decidual or placental cells. The relation established between those two factors of new formation is what is known as placental development. The manner in which this relation is established gives rise to the different forms of the mammalian placenta.

Dr. Alexander Simpson, of Edinburgh, spoke of the value of the paper and sketched the development of the placenta from the lowest type, where the foetal and maternal surfaces were simply laid together, and were separated at parturition, to the complicated interdigitation in the higher animals, and the highest type as found in the human female, where, at the time of delivery, the maternal and foetal portions came away together, leaving beneath it only the basal portion of the uterine mucous membrane.

Dr. E. Paul Sale, of Aberdeen, Miss., read a paper on the **Management of Pregnancy, with Reference to the Prevention of post-partum hæmorrhage**, in which he strongly insisted upon the value of prophylaxis, undertaken months before delivery, during which time the patient should be under the supervision of the accoucheur. Some of the predisposing causes and their treatment are as follows:

1. Hæmophilia, abnormal tenuity of the wall of the capillaries—Use stimulating oils, as turpentine or oleum origanum. Matico, liquid extract, also good. Ergot and allied drugs no value.
2. Anæmia, from various causes—Fluid extract stylohadsis, cimicifuga racemosa, salix nigra, etc. Faradization of the abdominal muscles for ten minutes daily.
3. Atonic debility, from rapid childbearing—Exercise, tonics, quinine, strychnia, iron, fresh air.
4. Laceration of cervix, cancer, fibroma—Let alone, except before third month.
5. Intemperance—Moral measures (what success?).
6. Heart disease—Gelsemium.
7. Plethora—Dietetics, salines.

Dr. H. B. Hemenway, of Kalamozoo, Mich., had not been able to diagnose *post-partum hæmorrhage* many months before labour. He asked what was the relation of late ligation of the cord to *post-partum hæmorrhage*. He strongly suspected that it tended to prevent such an occurrence, and his explanation was as follows:—There is no direct connection between the maternal blood-vessels and the placenta; if the cord is ligated late, or if only the foetal portion were ligated, blood flows from the placenta. The cord is normally attached near the centre of the placenta; if then, blood is extracted, the placenta must shrink and the edge will first become detached. If blood is not extracted from the placenta, it is more rigid, and as the uterus contracts the centre is likely to be first detached. A sack is thus formed which fills with the maternal blood, and the mouths of the uterine vessels do not firmly close. When the placenta is delivered, this accumulated blood rushes out and the maternal vessels again bleed.

Dr. W. W. Jaggard, of Chicago, calls attention to the following propositions:—

1. Late ligation of the cord is always indicated in the interest of the child—when not contra-indicated in the concrete case. The researches of Budin have demonstrated that when the cord is ligatured, when it ceases to pulsate, the child receives seventy-five grammes of blood—lost when the pulsating cord is tied. The relation of late ligation of the cord to the prevention of *post-partum hæmorrhage*, to which the gentleman from Michigan has called attention, is of great interest, if it be a fact.
2. The best prevention of *post-partum hæmorrhage* is to secure retraction of the uterus, by keeping the hand on the fundus uteri from

the moment the child begins to pass through the vulvar outlet until the muscular fibres have rearranged themselves—about one hour after expulsion of the placenta. Kucher, in his admirable book, has called attention to friction over the fundus twice daily during the first two days of the puerperium. This is the practice in Vienna. There is little danger of dislodgement of a clot in the uterine sinuses, or interruption of the process of puerperal thrombosis, by this procedure. It is also an excellent prophylactic against resorption of septic matter.

Dr. George Wheeler Jones, of Danville, Ill., read a paper on **Dystocia from Rigidity of the Cervix and its Management.**—After a consideration of the various conditions which might cause rigidity of the cervix, he spoke of the most important—spasmodic contraction—Here opium was most valuable, together with chloroform and Barnes' dilators, if quick dilatation was necessary. Sitz baths, warm vaginal douches, delivery in a warm room, morphia hypodermically, quinine where there was malaria, salicine in rheumatic cases, and electricity were all useful. He would never use chloral, as it was dangerous to mother and child. He then detailed some original investigations into the medicinal action of gassypii radix, delphinium, and ipecacuanha.

Dr. A. F. A. King, of Washington, D.C., called attention to the fact that the thinning of the uterine segment and the obliteration of the cervical canal, conditions which led to the rigidity of the cervix, were abnormalities. When the uterus and child maintained during pregnancy their normal lateral obliquity, the canal of the cervix from the external to the internal os will remain unobliterated until full term, which is the normal condition both for primiparae and multiparae. Under the same normal circumstances the great thinning of the lower uterine segment, the tearing of the decidua mucosa membrane, the "formation of a new cervical canal," and the other tissue-changes observed by Bandl, will be absent during pregnancy. They are abnormal. They may nevertheless occur during labour from abnormal mechanical obstruction to delivery. Dr. King also objected to the use of chloral.

Dr. Brooks H. Wells of New York, did not agree with Dr. Jones concerning the great danger to the unborn child from the use of chloral. In about one hundred cases out of between six and seven hundred which he had had under his charge, or had witnessed, it had been used both as an anæsthetic, where the first stage had been unusually painful, and in spasmodic rigidity of the cervix, and in no case had he seen any harm accrue to mother or child, but only the most gratifying results. He always used the precautionary measure mentioned by Dr. Jaggard, viz., to keep himself informed of the condition of the uterus by a hand placed over the fundus, slight rotary friction overcoming any possible tendency to relaxation, and had never had any serious post-partum bleeding, either with or without the use of chloral. Its administration might, in full doses, blunt the pains somewhat. He was accustomed to administer the drug in ten to fifteen grain doses, by mouth or rectum, until this result was attained—usually from two to three doses. He considered morphia and the hot douche important agents in treating the class of cases mentioned.

A paper by Dr. John H. Wilson, of Chicago, Ill., entitled "Puerperal Uræmic Amaurosis," was read by title.

The section then adjourned, after passing a vote of thanks to Professor Simpson for the felicitous and able manner in which he had presided.

Dr. Henry O. Marcy, of Boston, the President of the section, read a paper on the **Histology and Surgical Treatment of Uterine Myoma.**—The author presented an interesting array of micro-photographs. He showed the multilobular growth, the capsule the multilobular growth, and the parts at which they lie in juxtaposition; the histological relation of the growth to the uterus; the vascularization; the first injection they were able to make into a fibroid tumour; and discussed the bacilli discovered by Dr. Nelson, of Boston, which he termed bacillus Nelsonii. He showed a number of other cuts, and the specimen of a tumour which he had removed from a woman per vaginam, but which he would not attempt again, on account of its size; exhibited some instruments for the operation of removal of fibroid tumours, of his invention, and discussed the shoemaker's stitch. Illustrations were thrown on the screen by Drs. Martin, Clark, Nelson, and Hewson.

Dr. Caleb R. Reed, of Middleport, O., read a paper on **Intra-Uterine Stem Pessaries**, in which he favoured very much their use for promoting the flow of the menses in cases of local origin, and especially those where there was an ill-developed uterus. He thought that this instrument should come in the list of emmenagogues, and that it should not be condemned with the arrogance which generally accompanies its discussion.

Dr. Daniel T. Nelson, of Chicago, read a paper on the **Treatment of Uterine Myoma, by means of Ergot.**—The author had gone to

much pains to gather statistics from the profession, and made a good argument for this mode of treatment.

A paper by Dr. M. D. Spanton, of Hanley, England, was read by Dr. Eddowes, of Salop, England, on the subject of **Cystitis in Woman.**—Local conditions leading to cystitis in woman, among which are enumerated diseased states of the uterine appendages, bands of adhesions dragging upon the bladder, and some of the affections causing obstruction to the passage of the uterine, which are often obscure and trivial in themselves, are not infrequently overlooked.

Dr. William L. Reid, of Glasgow, Scotland, read a paper on the **Remote Results of Shortening the Round Ligaments.**—He had performed the operation eighteen times. He gave the opinions of the authorities, mostly British, and which were mostly unfavourable to the operation. The discussion which followed this paper was also rather unfavourable to the operation.

Dr. J. H. Kellogg of Battle Creek, Mich., read a paper on **Alexander's Operation**, and reported twenty cases. He favoured the operation.

Dr. W. C. Wade, of Holly, Mich., read a paper on **Displacements of the Uterus**, his paper consisting of thirty-nine terse statements about displacements.

Dr. Joseph Taber Johnston, of Washington, D. C., read a paper on **The Treatment of Commencing or Threatened Peritonitis by Brisk Purgation.**

Professor Vulliett, of Geneva, Switzerland, had two papers, "Progressive Uterine Dilatation" and "The Buried Suture with Iodized Silk in Vesico-vaginal Fistula." They were read in English by Professor Cordes, of Geneva.

Dr. Addinell Hewson, of Philadelphia, Pa., read a paper on **Abdominal Surgery.**

Dr. E. H. Tredholme, of Montreal, Canada, read a paper on "Extirpation of the Uterus for Bleeding Myoma."

A number of papers were read by title and the Section adjourned.

V.—SELECTIONS FROM ITALIAN JOURNALS.

By H. HANDFORD, M.D.

Rivista Internazionale, April, 1887. Pitres e Vaillard. **Neuritis, caused by the Injection of Ether in proximity to the Nerve Trunks of the Limbs.**—For a long time ether has been used subcutaneously as a rapidly-acting stimulant in emergencies; and, usually, if it does not result in as much benefit as one would hope or expect, at any rate, it does no harm. But in a certain number of cases, already sufficiently numerous, it has been followed by cutaneous anæsthesia and persisting motor paralysis, as well as marked trophic disturbances. Some experiments carried out in 1877 by Ocounkoff have clearly shown that this paralysis is due to a neuritis. If half a cubic centimetre of ether is injected deeply into the cellular tissue, between the inner and outer muscular masses on the back of the thigh of a rabbit, motor and sensory paralysis in the portion of the limb below the point of injection follows at once. The greater part of the muscles of the leg and foot are paralyzed, so that in walking the limb is dragged along as an inert mass. Trophic changes soon follow, and are indicated by oedema, ulceration of the foot and toes, and falling off of the nails. The anæsthesia and the motor paralysis comes on at once, and persists, with little or no alteration, for several weeks or months. The symptoms thus produced so closely resemble in their nature and distribution those following section of the nerve, that one is led to suppose that the ether exercises a local destructive influence on the nerve trunk. On examination of the nerve itself it is found that this is so. Above the point of injection the nerve undergoes no change. At the point of injection the changes are very marked, but vary according to the length of time that has elapsed since the injury. They are essentially destructive in character, and are indicated by breaking up and absorption of the white substance of Schwann and disappearance of many of the axial cylinders. Below, there is typical Wallerian degeneration. The practical outcome of this is that in injecting ether the neighbourhood of the nerve trunks should be avoided, and that the injection should be into the subcutaneous tissue, and not deep.

Mikulicz. **The Surgical Treatment of Stenosis of the Pylorus.**—Without being aware of the plan adopted by Heinecke, the author recently operated on a case of cicatricial contraction of the pylorus. At first the result appeared likely to be favourable, but after three days the patient died. The cause of death was frequent hæmorrhage, which came from an ulcer involving the pancreas. This was touched by the thermo-cautery, but without stopping the hæmorrhage. Resection could not have been practised in this case, because it would have been necessary to have taken away a portion of the pancreas, and gastro-enterostomy would have left the bleeding point untouched.

Kümmel. The Treatment of Tubercular Peritonitis by Laparotomy.—The author reviews this operation from the first case where Sir Spencer Wells, through an error in diagnosis, performed laparotomy for tubercular ascites, with the result of curing the patient, up to the present time. Including two cases of his own, of which he gives some particulars, he analyses thirty cases operated on by various surgeons. In more than twenty-five there was more or less improvement, which in some cases was permanent.

Lo Sperimentale, December, 1887. **Piperno. Laparotomy in a New-born Infant.**—The author was called to see a new-born male child with an incomplete development of the abdominal parietes. There was an oval opening, about two and a half inches in its long diameter, to the margins of which the umbilical cord was attached, forming an inverted funnel. Into this the intestines escaped, covered only by a thin layer of peritoneum. It was clearly impossible to expect to treat this hernial protrusion successfully by any kind of protective apparatus. It was also evident that in its then condition the child could not live; and, as it was otherwise well formed, the author, yielding to the entreaties of the parents, determined to operate, notwithstanding the apparently poor chance of success. Accordingly, at eight o'clock in the evening, using full antiseptic precautions, the margins of the opening were "refreshed," any vessels being tied before being cut, because of the importance of keeping the loss of blood as small as possible. Unfortunately, while the sutures were being put in, the child began to cry, and the peritoneum gave way, allowing the intestines to escape. This rendered the operation both more serious and more difficult. The intestines were wrapped in a flannel wrung out of a warm one and a half per cent. carbolic solution, and were eventually returned into the abdominal cavity. The wound was closed, and a Listerian dressing applied. The child was much chilled during the operation, which was performed in the month of December, in a country cottage. Warm applications were ordered. Next morning the child had passed urine, and was in good condition. The temperature in the rectum was 98.6. In the evening, as the bowels had not been moved, an enema was given, which was followed by a natural motion. The temperature remained normal till about midnight, when it rapidly fell, and death took place. Unfortunately, the friends would not permit any *post-mortem* examination to be made, so that whether death was due to shock or to peritonitis was not ascertained.

Riforma Medica, vol. 4. **Lamperties. On the Parasitic Nature of Cancerous Tumours.**—Experiments were made with twenty-eight tumours: two encephaloid, five epithelioma, four scirrhus, one adenoma, four sarcoma, two villous cancer, seven fibroma, and five lipoma. Tubes of agar-agar and of gelatine were inoculated, and kept some at a variable temperature, and some at a fixed temperature. Those inoculated from encephaloid, epithelioma, scirrhus, sarcoma, and villous cancer, produced rounded colonies of bacilli in from two to ten days. The bacilli from encephaloid developed most rapidly. The blood of a patient suffering from an encephaloid tumour also gave rise to colonies identical with those inoculated from the growth. The blood in cases of epithelioma gave negative results.

Gazz. degli Spedali, December, 1887. **Whitehouse. A case of Poisoning by Antipyrine.**—The author gave seven and a half grains of antipyrine in a drachm of syrup to a young child. In two or three minutes the child was taken with severe pain in the bowels, so that it constantly rolled and twisted about. In a short time a copious eruption of urticaria came out, and considerably increased the child's discomfort. Vomiting was excited by warm water and by tickling the pharynx, but the child remained in great danger. Fortunately, the author recollected the antagonistic action of atropia, and gave a subcutaneous injection of gr. $\frac{1}{10}$. This was followed by the best results, and the child was soon relieved and free from danger.

Orlowski. Extirpation of the Spleen.—This, says the author, brings the number of operations for the removal of the spleen already published up to thirty-nine. Of nineteen cases for leucocythæmia, only one survived. Of the remainder, nineteen were removed for chronic enlargement, and one for sarcoma. Of these twenty cases, seven died and thirteen recovered. The most serious difficulty in these operations consists in the adhesions to the diaphragm, and the consequent hæmorrhage in separating them. The best way of avoiding this is to leave a portion of the capsule of the spleen adherent to the diaphragm, and if necessary, some of the splenic substance also. Orlowski's patient was a lady, aged thirty-six, who had borne three children. There had been a large, hard, indolent abdominal tumour since early childhood. In April, 1885, ascites developed and rapidly increased. The patient was tapped, and a large quantity of clear thin fluid removed. Then the greatly enlarged, indurated, but movable spleen could be felt. At the end of June the operation of splenectomy was performed. The spleen was adherent to the omentum, which was

divided between double ligatures. In separating the adhesions to the diaphragm three vessels had to be tied. The pedicle was treated with a wire clamp, after the method of Cintrat, and was fixed to the abdominal wound. The patient died on the fifth day after the operation, and no *post-mortem* could be obtained. The spleen measured thirty centimetres in length and eighteen centimetres in breadth.

VI.—SURGERY.

DERMEPENTHESIS, OR ANIMAL SKIN-GRAFTING.

By G. CADOGAN-MASTERMAN, M.D.

It is to be regretted that the practice of skin-grafting, which gives such excellent results, should be attended with so many inconveniences. The donor, as I have often personally experienced, finds the momentary "snip" rather painful, and the little sores are some days in healing. A sensitive patient does not like giving the grafts himself, and his friends, although eager enough to provide them the first time, are seldom willing to repeat the donation, and there is the danger if alien skin be used of conveying local or even constitutional disease. And if the surface to be covered be large, the process is extremely tedious, and often disappointing. Frog's skin has been used as a substitute, but these amphibians are so repulsive to most people, and especially so to women and children, that after two trials I gave it up, and the more so because it utterly failed in both cases, and sought for some other source which would avoid the inconveniences, and yet be generally available, and I believe I have found it in the skin of the rabbit. And as the term human or rabbit skin-grafting is somewhat awkward, I would suggest the substitution of the above, from *Δέρμα* and *ἐκτένσις*.

I tried this plan for the first time in January, 1885, when I had two large superficial wounds to cover, and the patient himself was so unwilling to furnish the grafts, and his household, after a few experiences, so stoutly refused to contribute any more, that I was forced either to trust to the slow process of granulation, and probable contraction, or to find a more manageable supply, and a young wild rabbit I saw in the kitchen suggested its possible source. The case itself was a singular one:—A young farmer was riding home from market, at a smart pace, on a restive horse one dark November evening; he was on his wrong side, and at a turn in the road came into collision with a cart going in the opposite direction. The point of the near shaft struck him on the inner side of the left thigh, nearly transfixing it, and then, as he fell from the saddle, ripped it open as far as the groin. After a few minutes' confusion he was helped on his horse again, and accompanied by a passing tramp rode slowly about a mile home, fully convinced, he told me, that his belly and not his thigh had been torn open. I saw him shortly afterwards: there was a ragged, lacerated wound, extending from the middle of the thigh to Poupart's ligament, filled by a mass which I found to be a portion of his woollen drawers, about three inches of the centre of the *sartorius* muscle and blood clot; the two former had been driven through a rent in the *adductor longus*, and formed a large swelling at the back of the limb. On clearing this away the femoral sheath was found bared for three inches; it had escaped being torn by a miracle. Healing went on rapidly; but a large piece of integument sloughed away anteriorly, and still more at the back, and left the surfaces I had to cover, and did cover most successfully.

The second case was an ordinary one of an ulcerated leg, in which the plan again answered very well. But the third was somewhat unusual:—A middle-aged tradesman who had been drinking to slight excess for some years, came to me with recent traumatic orchitis. The pain and swelling were excessive, so morphia was given, three leeches applied, and an ice-bag. In the night acute *delirium tremens* developed, and when violently struggling to escape from the grasp of two neighbours who were trying to keep him in bed, the swollen scrotum was severely bruised—I think knelt upon—by one of the men. The next morning it was black and cold. Poultices were applied, and so on, but in a day or two the whole of the integument sloughed away from the root of the penis to the perinæum, leaving the pouch of the testicles exposed, and covered only by the pale pink lattice of the *cremaster* muscle. When the wound had been cleaned, there was a border of but half an inch wide of the scrotum left in a healthy condition, and the case was complicated by the extremely bad state of the patient's health generally, and extensive bed sores. I found, however, that a circular piece of skin, two inches in diameter, would just cover the testicles; and, with little hope of success, again tried the rabbit as its source. A young one was procured, the area marked out with ink on its previously-clipped abdomen, the animal killed by a blow on its neck, and the piece of skin rapidly dissected off and applied on the clean wound surface, pressed closely down, covered with a piece of lint dipped in hot water, and then with a fair-sized linseed-meal poultice. The latter was in turn kept hot without removal by an india-rubber hot-water bag, which was frequently emptied

and refilled. At the end of forty-eight hours the transferred skin was cautiously examined, and found to be adherent. A fresh poultice was applied and reinforced as before for three days longer, when the outer layer came away with the fur, leaving a firm, smooth integument, looking more like the mucous lining of the lips than ordinary skin, and when I last saw it in May, 1886, so it remained.

The fourth case was an unhealthy ulcer after a very tedious illness, *morbus coxae*, and therein after many trials with rabbits of all kinds and ages, the plan failed utterly.

The last in which I have had an opportunity for trying it was a terrible burn, which destroyed the skin, and in places the superficial fascia over the back, arms and thighs of a child of five years. The admirable carbonate of soda treatment relieved the pain like a charm, and, as fast as I could get portions of the wound clean, pieces of rabbits' skin, about the size of a shilling, were inserted, and two-thirds at least adhered. The poor child was under every disadvantage except plenty of fresh air, and, when more than half the surface was covered, unfortunately died from peritonitis (August 1st, 1887) three months after the accident. It was most interesting in this sad case to compare the rapidity with which the wound was covered artificially with the slow process of natural growth from its margin.

In order to ensure success, some precautions must be used: I found young wild rabbits by far the best; their skin is very thin, it separates readily, and there is no fat. Only a small piece, at least with one pair of hands, can usually be taken from each, for, although the animal is quickly killed in the customary manner by a sharp blow at the back of the neck before removing the skin, this must obviously be alive to be of any substitutional value. If it were not for an obstructive Act the best plan would be to chloroform the animal, dissect away as much skin in successive portions as one needed, and then kill it before it recovered consciousness. I have not tried the alternative, but I dare say the skin of the common cavy would answer as well if the now useless little beast could be killed as instantaneously as the other rodent, or were anæstheticized under licence.

The wound must be healthy and perfectly clean; dilute nitric acid lotion is, I think, the best preparative. The instruments must be sterilized—I prefer by dipping the blades into caustic potash solution, and then rinsing in recently boiled water. Not a moment must be lost in the transference, and the graft must be kept moist, not sodden, thoroughly warm, under gentle equable pressure, and not disturbed for forty-eight hours. There is no need to remove the fur, it came away in every case within a few days.

The term I suggest is, if inexact, at least unobjectionable.¹ The transferred skin can hardly be said to be engrafted or to grow; the surface layers, epithelial as well as dermal, obviously do not, but possibly the superficial fascia may do so; but I consider that it acts by influence rather than substitution, in some way so coercing the errant granulation cells, that instead of degenerating into pus, they coalesce into integument under the smooth, soft, and possibly still living shield. I noticed in many patches that the newly-formed skin was sensibly depressed below the level of the surrounding granulations, as if the growth of the latter had been checked, and their apices flattened into a continuous layer. Prolongations of new skin could often be seen starting from the limb of the circles, but they were never so marked nor so vigorous as from grafts of human source, although often sufficiently so to bridge over the space between two neighbouring discs very rapidly.

The advantages of this modification of M. Reverdin's plan of skin-grafting introduced, I believe, in 1869, are: That the patient is spared all pain himself as well as seeing it inflicted upon others; that in place of minute centres of new growth being established, surfaces up to at least two inches in diameter may be covered at once; that in the case of burns this rapid tegumentation not only prevents much suffering but greatly reduces the probability of subsequent contraction; that alien skin may be unhesitatingly employed: and that the duration of healing is reduced to a minimum.

With only four successful cases, its value is, of course, still problematical; but the results, so far, have been so encouraging, that I trust the plan may be worth the trying on a larger scale than the opportunities of private practice have afforded me.

VII.—DISEASES OF THE SKIN.

Formulæ abstracted from advanced sheets of "A Practical Treatise on Diseases of the Skin," by John V. Shoemaker, A.M., M.D. Appleton and Co., New York.

¹ The word should properly be dermatopenthesis, but I think the contraction is convenient, and I hope permissible.

INTERNAL.

BITES AND STINGS OF INSECTS.

Take of Oil of sassafras 2 drachms.

Dose: two to ten drops on sugar or in syrup every two to four hours.

CARBUNCULUS—CARBUNCLE.

Take of Carbonate of ammonium 2½ drachms.

Fluid extract of coffee ½ ounce.

Syrup 4 ounces.

Dose: one or two teaspoonfuls every two or three hours.

CARBUNCULUS—CARBUNCLE.

Take of Antipyrine 200 grains.

Make into twenty powders.

Dose: one powder in water every one or two hours.

CARBUNCULUS—CARBUNCLE.

Take of Sulphate of quinia 30 grains.

Sulphide of calcium 10 grains.

Mix and divide into twenty pills.

Dose: one or two pills every three or four hours.

CARBUNCULUS—CARBUNCLE.

Take of Tincture of chloride of iron 1½ ounces.

Glycerin 1½ ounces.

Sulphate of quinia 1 drachm.

Mix. Dose: one teaspoonful in water every two or three hours.

COMEDA—SEBACEOUS PLUG OR GRUB.

Take of Dialyzed iron 1 ounce.

Glycerin 2 ounces.

Castor-oil 2 ounces.

Mix. Dose: one to two teaspoonfuls night and morning.

COMEDO—SEBACEOUS PLUG OR GRUB.

Take of Cod-liver oil ½ ounce.

Sulphuric ether 20 drops.

Mix. One dose: to be taken three times a day.

CHANCROID.

Take of Syrup of iodide of iron 1 ounce.

Chlorate of potassium 2½ drachms.

Glycerin 2 ounces.

Water 1 ounce.

Mix. Dose: one to two teaspoonfuls every two or three hours.

CHANCROID.

Take of Tartrate of iron and potassium 4 drachms.

Aromatic spirit of ammonia 2 drachms.

Water 3 ounces.

Mix. Dose: one teaspoonful in water every three hours.

CHANCROID.

Take of Sulphate of quinia 30 grains.

Compound powder of ipecacuanha .. 30 grains.

Mix and divide into thirty pills.

Dose: Two pills every two or three hours.

DERMATALGIA—NEURALGIA OF THE SKIN.

Take of Fluid extract of gelsemium 2 drachms.

Dose: two to five drops in water every three or four hours.

DERMATALGIA—NEURALGIA OF THE SKIN.

Take of Croton Chloral hydrate 36 grains.

Glycerite of tragacanth a sufficient quantity.

Mix and divide into twelve pills.

Dose: one pill every two or three hours.

ECZEMA, ACUTE.

Take of Tincture of aconite root 2 drachms.

Water 6 drachms.

Mix. Dose: four to eight drops every hour or two.

The Treatment of Acne.—Lassar (*Therap. Mntshft.*, No. 1, 1888) recommends for all forms of acne the following paste:

Naphthol 10 parts.

Precipitated sulphur 50 "

Vaseline or lanoline } each 25 "

Green soap

This is to be spread upon the skin to the thickness of the back of a knife-blade, and left on for fifteen or twenty minutes, when it will cause a little burning. It is then to be wiped off with a soft cloth, and the

skin powdered with talc. The skin soon becomes inflamed, then turns brown, and finally peels off. The desquamation can be hastened by the application of Lassar's paste with two per cent. of salicylic acid. When the desquamation has ceased, the acne will be found to be greatly benefited.

Treatment of Secondary Syphilitic Baldness.—This affection is characterised by an extensive and persistent loss of hair from the scalp, eyebrows and eyelids, independent of any eruption of the skin, and distinct from the tertiary syphilitic alopecia resulting from cicatrization of ulcerations. It may be successfully treated by the topical application of the following ointment:

Rx.—Hydrargyri iodidi rubri.....gr. v.
 Attar rosæ.....mij.
 Ol. amygdalæ.....mij.
 Unguenti simplicis.....3j.—M.

For the eyebrows and eyelids, where the skin is more sensitive, the mercury should be reduced to one half the quantity. This treatment is usually satisfactory, after about a month's trial.—*Pacific Medical Record*.

Pruritus of the Anus.—This troublesome affection has been found by Bangs (*New York Medical Monthly*) to be due in some cases to irritation in the genital organs, as by stricture of the urethra, or by acute or chronic enlargement of the prostate, and he has succeeded in curing the pruritus by curing the source of irritation. In one case, occurring with acute prostatitis, the intense itching was cured by hot water rectal injections. In another case of intense pruritus, which had resisted all attempts at relief, a very sensitive condition of the urethra was found, dependent upon prolonged sexual intercourse. The patient was cured by the passage of a sound, and by correcting his bad sexual habit. Several other interesting cases are reported, all illustrating the connection in some cases between the itching of the skin and irritation in the genital tract.

Paraldehyde Vehicle.—The following is recommended by Dr. R. G. Eccles:

Rx.—Paraldehyde
 Almond oil.....āā 3ij.
 Chloroform.....m x.
 Oil cinnamon.....mij.—M.
 Sig.—Half to be taken at bedtime.

Iodine in Enlarged Glands.—The following has been found of decided value in the treatment of swollen glands:

Rx.—Tr. iodi.....3ij.
 Oleum lanæ.....3ij.—M.
 Sig.—Rub in over affected parts.—*Medical Summary*.

Multiple Neuritis as a Sequel of Erysipelas. By W. Browning, M.D., Brooklyn (*The Brooklyn Medical Journal*, vol. i., No. 1, January, 1888).—Dr. Browning, enumerating the various causes that have been assigned for multiple neuritis, points out that erysipelas is not among them, at the same time that he relates two cases in illustration of his view of erysipelas as a cause. The first case is that of a German woman, aged sixty-seven years, who in March last was attacked by erysipelas of the head and face. In about a week or ten days after this had subsided, she began to have indefinite pains in her limbs. At this time she could stand, with assistance, unsteadily, and under great distress. Knee-jerk was absent on both sides, as was also plantar reflex. No faradaic reaction. The affection soon extended to the upper extremities. The temperature ranged from 100 $\frac{3}{4}$ ° to 101 $\frac{3}{4}$ °. She was sleepless; narcotics were of no avail. For a few days in May she improved, but suffered a relapse. Some degree of mental feebleness became manifest, with insomnia, restlessness, despondency, loss of memory, and delirium. At the date of the last report (September 24th) the patient continued in much the same condition. The other case was that of a locomotive engineer, aged thirty-three, who suffered from erysipelas of the arm, after a burn. After the wound had healed, and the patient had returned to his work, he found the use of his hand impaired, so that he could not fully extend the fingers, nor flex the thumb on the palm, and considerable atrophy of the muscles of the forearm ensued. This state of the limb had continued up to October in last year.

The Spirit of the Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, February 28th. There was an excellent discussion On the Radical Cure of Hydrocele, with Notes of Two Cases of Excision of the Tunica Vaginalis followed by Recurrence of the Hydrocele.—Mr. HENRY MORRIS

described the methods of treatment by injections, tents, setons, caustics, incision and excision. His conclusion that there did not seem much difference between injection and incision, or excision, in the duration, treatment, or the certainty of result, is one that will be shared in by most surgeons.—Mr. POLLOCK, president, said that hydrocele was very capricious, and he had known of a case where there had been no recurrence after one tapping, whilst cases that had been treated surgically by injection and by incision recurred.—Sir JOSEPH FAYRER gave his Indian experiences where hydrocele was common. He favoured the treatment by tincture of iodine undiluted, two drachms, as the cure for simple hydroceles. For a certain class of cases excision was necessary.—Mr. WILLETT related a case where two drachms of the undiluted tincture of iodine had been injected with only temporary relief, the fluid returning. Mr. Bryant said he generally used two drachms of an equal mixture of tinct. and liquor iodine undiluted, but no fluid should be left in the sac, and he had very few failures under this plan. Mr. Bryant said that excision was useful in certain cases, but he certainly did not favour it as a general plan.—Mr. TREVES used Curling's solution of iodine, two drachms. In tracing the subsequent history of the cases he found a recurrence in at least twenty-five per cent.; but he also found that after incision and excision there was the same percentage of failures.—Mr. WALSHAM had failures after the injection of the undiluted tincture of iodine. Radical operation seemed to be too serious for working men, who could be tapped without risk every six months.—The conclusion to be drawn from this discussion is that there is no safe radical cure for hydrocele.

ROYAL ACADEMY OF MEDICINE, IRELAND.—At a meeting of this Society Dr. SMITH read the report of the Rotunda Hospital, Dublin, for 1887. The hospital is advancing on the new lines of teaching, and since a gynaecological ward has been opened it has added to its usefulness. The gynaecological wards contain thirty beds. Four hundred and fifty patients were received during the year, being an increase of 106 over the previous twelve months. It was remarkable that retro-uterine hæmatocele occurred eight times, carcinoma thirty, and serious tubal disease only once. All the cases of carcinoma were too far advanced on admission into hospital to justify any radical operation. Nothing was left to be done except to palliate by thorough curetting down to the muscular coat of the uterus, and injecting equal parts of the liniment and tincture of iodine. Abdominal sections were performed eight times for the removal of ovarian tumours, once for the removal of a double ovarian abscess, and once in a case of peritonitis, which proved carcinomatous, making in all fourteen, with four deaths. The uterus was curetted 105 times, including incomplete abortions (18), carcinoma (30), and endometritis (57), without any reaction following, showing that when properly performed this operation was entirely without danger. The bimanual method of examination was practised and taught, with the patient in the dorsal position on a Schroeder chair. The uterine sound has been found most useful during the year as an aid in diagnosing many diseases of the endometrium. It detected with accuracy the patulous condition of the internal os, whether the mucous membrane were hyper-sensitive, thickened, or roughened, and it would demonstrate its tendency to hæmorrhage if that condition were present. Schulby's pelvic diagrams were used to encourage accuracy of diagnosis, and Wyder's transparent plates for illustrations of pathological conditions. Antiseptic solutions were only employed where the hands or instruments had been engaged in septic cases. The stages of disinfection practised were: For the hands, (1) thorough scrubbing for a couple of minutes with carbolic soap and a nail brush in a five per cent. carbolic solution; (2) rinsing in carbolic solution; (3) soaking for one minute in corrosive sublimate solution, 1 in 500. All instruments were disinfected by boiling in a five per cent. carbolic solution. For some time past ordinary Varty water had been employed for the usual operations about the uterus and the vagina, and as good results had been obtained as when solutions of carbolic acid or corrosive sublimate had been used for the purpose.

LEEDS AND WEST RIDING MEDICAL CHIRURGICAL SOCIETY, February 17th, 1888, Dr. BELL (Bradford) brought forward the very important subject of the prevention of ophthalmia neonatorum. The Committee of the Eye and Ear Hospital supply the registrar of births with slips of paper on which are printed directions on the washing of the eyes of the newly-born. These slips are given to persons registering births. The total cost for the Bradford district did not exceed thirty shillings. If this system were adopted over all England the cost of the slips would not amount to more than £30. If it be true, seventy-two per cent. of the blind in England owe their sad condition to this preventable cause, then the Government ought in duty to take into their own hands the printing and distribution of these slips. Meantime

waiting for Government action, medical officers connected with eye institutions might adopt this system in vogue in Bradford, and thereby contribute most effectually to the prevention of what is one of the saddest afflictions.

* * * * *

OBSTETRICAL SOCIETY OF LONDON, March 7th.—At a meeting of the above society Dr. BOXALL read a paper *On Scarlatina during Pregnancy and in the Puerperal State*.—Dr. Boxall gave a brief summary of sixteen cases of undoubted scarlatina, and pointed out that in one case only were the scarlatinal manifestations associated with signs of septic poisoning. Forty lying-in patients were known to have been exposed to one or more of the above cases of scarlatina. This series is presented in a tabular form, giving the time and duration of exposure and the course of the puerperium. On this evidence it was apparent that such exposure resulted in no detriment to the puerperium. As it might be urged that the 300 patients or more admitted during the prevalence of scarlatina were to a greater or less extent exposed, a chart (together with the percentage tables from which it was constructed) is also appended. This indicated the morbidity (as judged by the temperature) prevailing not only during the whole scarlatinal period, but included, in addition, the three months which preceded the outbreak. From this it was evident that the prevalence of scarlatina in the hospital exerted no appreciable effect on other cases lying-in during the same period. The special value of local antiseptic measures in scarlatina during the lying-in period was discussed. The following conclusions were offered: 1. That infection by the poison of scarlatina *generally* produced in the puerpera a disease which presents *for the most part* the usual symptoms of scarlatina, and runs the ordinary course of the disease without the appearance of septic manifestations. 2. That the disease, in addition to the usual symptoms of scarlatina (to a certain extent modified), may *occasionally* present signs of septic poisoning; that, when present at the onset of the disease, pelvic inflammation and septicæmia may usually be regarded as accidental complications, but, at a later stage, such signs may be the expression of a septic process analogous to the secondary throat of ordinary scarlatina. 3. That *in rare instances* the disease may assume a masked form, in which the ordinary signs of scarlatina are absent, or so slight and evanescent as to escape observation; and that, in some such cases, the only manifestation of the illness may be found in signs usually referred to septic poisoning.

After referring in very brief terms to remedial measures, the author discussed the means which should be adopted to prevent the spread of scarlatina to pregnant and parturient women. He pointed out the advisability on the one hand of isolating all scarlatinal cases and disinfecting all contaminated articles, and on the other of shielding pregnant and parturient women from the many risks of scarlatinal infection which surround them, and, when possible, of removing such patients from any district in which the disease was prevalent. The influence of a third person as a vehicle of infection was discussed with special reference to the conditions under which it was likely to be exercised, and, finally, the measures which might be adopted to counteract that influence, were pointed out. He concluded finally, "that, as the poison might be carried not only directly by the hands, but also indirectly by the clothes and general surface of the body, and possibly by the breath, and subsequently given off into the atmosphere (from which it is inhaled by the patient); thorough washing and disinfection of the hands was not sufficient to insure protection, but that a disinfectant bath, a complete change of clothing, and active out-door exercise, should be also included in the necessary precautions, and that these measures should be adopted not only by the doctor, but also by all other persons who have been brought into contact with scarlatinal poison, and especially by the nurse, prior to attending on lying-in women or even visiting a patient who is advanced in pregnancy." Dr. Boxall's papers were accompanied by diagrams and tables, and this paper was the final one of a series.

Dr. DOLAN (Halifax) said that after twenty years' general practice, and after attending some thousands of confinements, he could not agree with the conclusions as to the personal treatment required by the medical attendant. Under the ordinary conditions of practice it would be impossible to carry out Dr. Boxall's recommendations. From personal experience he found that, contrary to the preconceived opinion, puerperal women did not contract scarlatina, even though exposed to the danger. In the homes of the working classes women were continually exposed. The puerperal death-rate did not rise in Halifax during scarlatinal epidemics. If medical men carried contagion they would be a danger to society, and if puerperal women so readily contracted scarlatina the only way out of the difficulty would be to establish two distinct classes of practitioners—one to attend labours only, and the other to attend cases of scarlatina. Under existing conditions, even were it practicable, such a system was unnecessary.—Dr. PLAYFAIR pointed out that scarlatina had been held to be peculiarly dangerous to

lying-in women, though it might run a perfectly normal course, and in some cases it was untypical. These opinions were not disproved by Dr. Boxall, whose patients were placed in the most favourable conditions. Dr. Playfair suggested a theory which would explain the significance of two forms of scarlatina: (1) As conveyed through the ordinary channels of infection; (2) as conveyed directly to the genital tract by the hands of the obstetrician or midwife, or by infected sponges, etc. He recalled to mind the outbreak of puerperal fever in the lying-in ward of King's College Hospital. It was coincident with erysipelas in the surgical wards, but which did not present symptoms of erysipelas in the women.—Dr. AUST LAWRENCE (Clifton) believed that these cases did not die of scarlatina itself, but from the infected lochia. He related a case in which the patient was saved by timely washing out of the uterus.—Dr. HERMAN was of opinion that scarlatina when conveyed to a lying-in woman produced scarlatina and nothing else.—Dr. BRAXTON HICKS reviewed the position he had taken many years back of scarlatina in puerperal women, and he was still of opinion that scarlatina was mixed with true puerperal fever or septicæmia, the scarlatinal element being masked or latent.—Dr. MATTHEWS DUNCAN was of opinion that we should be more careful as to words; it was one thing to speak of antiseptic, and another thing to talk about anti-scarlatinal. For antiseptic treatment might keep away the microbe of suppuration or septicæmia, but it would not ward off scarlatina. He believed in the theory that the so-called scarlatina of midwifery and surgery included more than one disease, but he regarded true scarlatina occurring within a few days of lying-in as a disease of enormous mortality. He had observed a red rash, with fever, which began around the wound made in opening a chronic inguinal parametric sinus. The rash spread, but there was no certainty that it represented scarlatina. Dr. Duncan did not believe in the commingling of scarlatina and puerperal fever. When the former disease raged in London, killing 250 a week, there was no increase of puerperal fever. This fact agreed with Dr. DOLAN's practical conclusions.—On the motion of Dr. GALABIN, the discussion on Dr. Boxall's paper was adjourned.

Medical Miscellanea.

The subject of our next illustration will be Dr. Bucknill.

* * * * *

Dr. Donald MacAlister, Fellow of St. John's College, Cambridge, will deliver the Croonian Lectures on "Antipyretics."

* * * * *

At Waldeck, Germany, a law has been adopted forbidding the granting of a marriage license to any person who has become addicted to alcohol.

* * * * *

A wooden case, containing a complete outfit of surgical instruments, has recently been discovered at Pompeii. Many of the instruments are said to bear a very close resemblance to those used at the present day.

* * * * *

We learn from Egypt that Dr. Schliemann and Professor Virchow have been entertained at Cairo by Dr. Grant Bey. They are expected to return to Berlin about May.

* * * * *

The annual dinner of the Medical Society of London took place at the Whitehall Chambers, Hotel Métropole, on Thursday, March 8th, Dr. Hughlings Jackson in the chair. Sir Thomas Crawford was also present.

* * * * *

The Countess of Dufferin's Fund has found another supporter in the Pegu Municipal Committee, who have provided in next year's Budget for two scholarships, at twenty rs. per month, to enable Burmese women to study midwifery, and the civil surgeon has been requested to look out for suitable candidates.

* * * * *

Two deaths are reported in the *Gazette Hebdom. des Sciences Medicales*, 4th March, after treatment by the method of Pasteur. (1) J. Mazoyer, age 4. St. Albain, bitten 6th December, treated at the Institute from the 12th December till the 7th of January; died on January 22nd. (2) Madame Delpech, Paris, age 52, bitten 23rd January; died on 17th February.

Dr. G. F. Cadogan-Masterman, Stourport, has published a small pamphlet of seven pages on Dermepenthesis, or animal skin-grafting, which opens out a new field of usefulness to the surgeon. Skin-grafting by the usual method has been attended by difficulties. Grafts from human beings are not always easily obtained. Dr. Masterman, after experimenting with frog's skin, has fallen back upon an animal so much used in experimentation—viz., the rabbit. We publish in another column a full description of the method.

Messrs. Baillière, Tindall and Cox, are to be congratulated upon the enterprise which prompted them to introduce to the profession in England, Wilkowskis' atlases, or super-imposed plates. They are intended for students, but we consider they are equally valuable to men in practice, as thereby they can keep up their anatomy. Dissection by the majority of men is out of the question, but by means of these plates the practitioner can at any moment refresh his memory. Part XI. has just come under our notice, and is illustrative of pregnancy at full term. The plate is admirably executed and has thirty-seven references. Accompanying the atlas we have a synopsis of practical obstetrics by Professor Pajot, translated by R. Milne Murray, Esq. Thirty pages. It is an excellent pamphlet, and rendered more valuable by some additional notes by the translator.

Should Dr. Murray's descriptive pamphlet not be found sufficient, Dr. Samuel Nall's Aids to Obstetrics can be recommended. It is an admirable summary of obstetrics, and we have no hesitation in saying that it is the best of the "aid" series. It consists of 137 pages of closely printed matter, with a good index.

The Dental Hospital of London, in Leicester-square, have announced a post-graduate course of demonstrations for registered doctors and dentists. We understand that it is intended to make the course of a very practicable character. Two demonstrations are to be given each day, and include such subjects as gold of various kinds, amalgam, and other soft stoppings; treatment of fractured maxillæ, of pyorrhœa-alveolaris, alveolar abscess, etc., all of which subjects are as interesting to the general as to the dental practitioner. In the report, which was unanimously adopted at the meeting on the 15th, the Managing Committee congratulated the Governors on the continued success and prosperity of the institution; also on the great benefits which the Hospital continues to afford to the suffering poor, 47,441 cases having been treated during the year 1887, a large number of them painlessly (under anæsthetics). It had been found necessary to further enlarge the Hospital by the purchase of the adjoining house for £3,500, increasing the mortgage debt on the Hospital to £5,500. There is still a deficit of £5,700 in the Extension Account, and the Committee specially appeal for funds to pay this debt which encumbers the charity, and curtails the benefits it would otherwise confer. The charity is unendowed, and increased funds would greatly extend its usefulness.

Henry Buchanan, *alias* Arthur Chadwick, *alias* Arthur Nelson, John Nelson, *alias* William Kay, *alias* Madame de Vere, of Cross Lane, Salford; John Wilson, draper's assistant, of Dunville-street, Byrom-street; Edward Thomas, described as a dispenser's assistant, residing in Lord-street, Chorlton-on-Medlock; and Raphael Shires, of Willow-street, Broughton Lane, were discharged on remand at Manchester, March 22nd, with conspiring to defraud different persons of various sums of money. Mr. W. Cobbett prosecuted on behalf of the police. Mr. Blair appeared for Shires and Thomas, Mr. C. M'Keand for Buchanan, Mr. A. T. H. Evans for Kay, and Mr. E. Desquesnes for Wilson.—Mr. Cobbett said that Buchanan and Kay were first prisoners arrested under a warrant charging them with attempting to obtain money by false pretences. The other prisoners were taken into custody subsequently, and all were now charged with conspiring together to defraud persons by falsely representing themselves to be experienced in the treatment of that which required a great amount of knowledge and skill. The following evidence was brought forward.—Mr. Cobbett said: A place of business was opened in King-street West, and one in Bridge-street. The books found in the possession of the prisoners at these addresses would form a very important part of the evidence to be given against the prisoners, for in them they spoke of their qualifications, experience, &c. These books had been sent to agents of the prisoners in various towns for distribution. The books were of an indecent character, and gave testimonials from numerous people who had been under the treatment of one or more of the prisoners. Some of the books have been distributed in the streets of Manchester. To show the genuineness of the books it was stated in one of them that they could be purchased from all booksellers in town or county, the price being

1s. each, but this was false. Mr. Cobbett next called the attention of the Bench to the fact that on one page of one of the books it was stated that Buchanan, or Chadwick, had been in the business for a period of twenty years. It also stated that he had an intimate acquaintance with a certain disease, for which he had a sure and safe remedy. As a matter of fact, this man did not commence business as a "specialist" until 1884, for previous to that he had been a betting-man, or a clerk to a betting-man, in Manchester. Shires, who sometimes had taken Buchanan's place, had followed a variety of occupations, while Kay had been a clerk, and Thomas a bookmaker's clerk. The place in King-street West, was described on the windows as the "Medical Institute—Nelson and Co.," and on the door was "J. Nelson, specialist," painted in large letters. In Bridge-street Shires and Chadwick seemed to be the leading spirits, but at each of those places the whole of the prisoners, he (Mr. Cobbett) would be able to prove, had taken an active part in the business. In some cases persons who had been under the treatment of the prisoners had paid as much as £5, £15, £20; and even as large a sum as £50 had been paid for a "specific" which was said to be very valuable. One person was charged £25 for a battery said to be worth a few shillings, and another paid £90 for treatment and medicine which could have been obtained for 25s. On one occasion a police constable went to the prisoner Kay, and was told that he was suffering from some disease, the fact being that the man was sound and healthy. For treating him Kay asked a fee of £5.—A number of witnesses were called in support of Mr. Cobbett's statement, and the prisoners were again remanded.

The above case suggests some thoughts. Are these men any more guilty than the persons who run the patent medicines and electro-belts (advertised so largely in the lay press), "to cure all diseases, where medical men have failed," etc.

If difference there be it is only in degree. The law in Germany is more stringent than ours, and patent medicines, or "cure alls," are there subjected to a rigorous censorship, and effectually suppressed.

The sale of patent medicines in England is marvellous. The poor working man, for whom we so officiously cater, providing for him *medicine and advice* for 2d. a week, readily pays his 3s. 8d. or 2s. 6d. for a bottle of Warner's Safe Cure, Mother Seigel, or other advertised nostrum, or parts with £1 10s. 0d. or 21s. for a piece of flannel, with a few metal discs sewn in; and then he coolly comes to us, and wants instantaneous and permanent relief for a few sous.

The Manchester specialists were only imitating the enterprising Holloways, Morrises, etc., and their books, filthy though they were, were advertisements of their filthy trade, the object of which was to make money. Testimonials they had, of course.

The extent of the advertising of some of the patent medicine vendors may be gathered from a statement in the *Medical Press and Circular*. Orders have been given "for Mother Seigel's Syrup, fifteen million chromo covers, and one million chromo box-tops; for Warner's Safe Cure, eight million chromo covers, and eighty thousand show-cards; for Howell's Golden Herb Pills, one million and a half of chromo handbills."

It is very singular that the religious papers are favourite mediums for the advertisement of quack remedies, and still more that the clergy are such strong upholders of the same. The reason, we suppose, is that we treat them so well. The profession, as a rule, attends the cloth free of charge, and is also obliging enough to help them in any charitable scheme.

We cannot prevent the public from spending their money as they choose. We may, however, legitimately object to recognise the plea that the working man is not able to pay a fair fee for medical advice (not for medicine), or that 6d. or 1s. dispensaries are at all necessary.

M. Jeffroy has related at the Academy of Medicine, Paris, a case of Friedreich's Disease. The patient had an incoördinate walk, like that of a drunken man, and was obliged to hold to surrounding objects for support; his heel was the first to touch the ground in walking. The foot presents no malformation, at least, in standing, but in sitting it has a tendency to assume a form of club-foot. The lower extremities manifest a slight degree of hyperæsthesia. Plantar reflex is intact, tendon reflex absent. There is a similar impairment of muscular power in the upper extremities. The patient eats grossly; writing becomes difficult, etc.

M. Féré relates (*Gazette Hebdomadaire des Sciences Médicales*, March 4th, 1888) a case of traumatic epilepsy cured by trephining. The patient, in battle, had been struck on the head by a small bomb-shell. Epileptic attacks followed. There had been no antecedent seizures. All medical means having proved of no avail, he applied three trephines, and found the internal table of the skull depressed. Since this operation (three months had elapsed) no epileptic seizure had occurred.

THE MEDICAL, DENTISTS', AND MEDICAL STUDENTS' REGISTERS. These Registers, which are in much demand, were published on the 21st instant, and copies may now be had from Messrs. Spottiswoode and Co., the Medical Council's Publishers.—The *Medical Register*, corrected and revised throughout from all available data, has had prefixed to it some additional preliminary matter of interest, in the form of statistics and tables. From the statistics it appears that, whereas the number registered in 1877 was but 940, the number registered last year was 1531 (showing an increase of 591); while the total number in the *Register* for 1876—the first year in which any such data as are now presented were ascertained—was 22,200, the number on the present *Register* is 27,246 (showing an increase of 5046), whereof about 66 per cent. were registered in London, 19 in Edinburgh, and 16 in Dublin. The number of pages in the present *Register* is 1172,—a large increase from the 335 paged volume that sufficed for 1859, the 548 pages for 1870, and the 598 pages for 1876.—The *Medical Students' Register* has prefixed to it similar tables and statistics, showing *inter alia*, for each division of the United Kingdom, the respective numbers registered in 1887 as having passed the several recognised examinations, and the numbers registered at each place of medical study.—The *Dentist's Register* has been subjected to a most thorough and searching investigation, a process already rendered absolutely necessary, owing to gross carelessness or neglect on the part of registered dentists. Soon after Midsummer, Inquiry-Letters, under section 12 of the *Dentists' Act*, were sent to all persons on the *Register*, and, three months later, nearly a thousand registered second Inquiry-Letters had to be sent, as prescribed in the cited section, to those who had not answered the first Inquiry. By this heavy labour, an unprecedented amount of errors has been disclosed and corrected. From the tables and statistics contained in the preliminary matter of the *Register* it appears that the unqualified dentists were, in 1879, 4806, or 91 per cent. of the whole, while the dental licentiates were 483; but in the present *Register* the licentiates have increased to 977, and the unqualified persons have diminished to 3889, or 79 per cent. of the total, thus showing already a decrease of 12 per cent.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "The Provincial Medical Journal," Horton House, Halifax.

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester; or to the London Representative, Mr. E. BELLA, 58, Charing Cross Road, W.C., to whom all communications respecting Advertisements should be addressed.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

ON SOME VERY OLD FRENCH REMEDIES.

To the Editor of "The Provincial Medical Journal."

SIR,—I found in an old French book, published some 400 years ago, entitled "Dictionnaire Botanique et Medicale," some exceedingly ridiculous, preposterous remedies for all "the ills that flesh is

heir to," nearly all of them most revolting and disgusting. But, as in a heap of rubbish the *chiffonier* often finds a diamond ring or a silver spoon, so I have found two remedies in that book which were, some centuries later, employed in England and in Germany. The "Poudre de Trois Poivres" suggested to the Ward family an imitation of that remedy for hæmorrhoids—a confection called "Ward's Paste," which had been so strongly recommended by Sir Everard Home and by Sir Benjamin Brodie. Whether or not the chemist of that time knew anything of analysis it is hard to say, but in this book are recommended two syrups for pectoral affections, "*Sirup de Chou Rouge*" and "*Sirup de Chou Jaune*." Hoffman, a distinguished physician in Germany and a clever analytical chemist, must have (many years after this book was published) caught up a copy, and saw at once that the agent in these syrups was sulphur. He then adopted the habit of prescribing for chronic bronchitis five grains of sulphur three or four times a day; and, aware that stomach flatulence disturbed the respiration of old people, he added to each dose of sulphur some black pepper. Later on, some itinerant French organ-grinder brought into Ireland a recipe for coughs, which was handed down from father to son, and it seems, is still used up to the present day. Not long ago, I met an old widow lady, who said she was troubled every winter or spring with an attack of chronic bronchitis, and on the last attack she had to occupy her bed. She informed me that on this last occasion an old beggarman, who in his travels through the country was in the habit of paying bi-annual visits to her kitchen, informed the servant that he could cure the old lady's cough. Her cook was quite incredulous, and having told her mistress that he was *positive* he could cure her, she told her cook to let him have his own way. "I'll let you know after awhile what *my cure* is, but, in the first place, boil for three hours some cabbages, and, after seeing some of the neighbours, I'll return when I think the cabbage is boiled." When he returned he chopped up the cabbage, emptied a whole cruet bottle of black pepper and sprinkled a quantity of salt over it, telling the cook to give the old lady a tablespoonful of this compound every three hours. The old lady declared to me that "in two days she was quite relieved from her cough." Now, you observe two ingredients of this beggar's compound were used by Hoffman—viz., sulphur and pepper. I don't know if Hoffmann added salt. . . . Sir Dominick Corrigan, arguing from the action of quinine on the asthenic congestion of the spleen in ague, recommended the use of quinine also in asthenic affections of the lungs. Now, considering that in the East Indies practitioners prescribed *pipérin* with success when quinine failed to relieve, why should not the piperine of Hoffman's or of the beggar's cure also relieve typhoid cases of lung disease occurring in old people or in broken-down constitutions? As I have alluded to sulphur in this paper, I will say a word about Bergeon's proposed treatment of phthisis by the insufflation of sulphuretted hydrogen per "rectum." Now, inasmuch as many people have rather a surplus supply of this gas in their intestines, some of which, unconsciously to themselves, may travel up occasionally through the œsophagus, and become absorbed by the lungs from the pharynx, thereby working out Bergeon's theory. I cannot conceive how a further supply of sulphuretted hydrogen should be sent up the rectum. Adapting an apothegm of Horace to Bergeon's theory, I say—

"Sunt certi denique fines

Quos ultra citraque, nequid consistere "rectum."

Yours obediently,

JAMES J. COPPINGER, M.D.

Kantuck, Co. Cork,
March 7th, 1888.

DOG BITES—A PERSONAL EXPERIENCE.

To the Editor of "The Provincial Medical Journal."

DEAR SIR,—Are you aware that your book on "Rabies" cannot be obtained through booksellers? I have tried to get it through them, and could not. I should be glad to know through whom I could get it, and if I knew the price, would forward postal order for the amount.

I have written at different times to several papers on the injustice of allowing those who do not keep dogs, and the public, to be injured by the dogs which other people keep. Of course, it is the duty of mankind to diminish as much as possible accidental and avoidable deaths, and to make life as long, as secure, and as happy as we can; for only in old age can it pass away without pain, laceration, and sorrow. Last summer, myself and another man being bitten by a dog which the town authority and veterinary surgeon, after *post-mortem*, declared to have been rabid, brought the subject of dogs and rabies forcibly to my mind; and I consider it my duty to do my part to prevent the happiness of human beings suffering from preventable evils arising therefrom.

For scientific purposes I may state what my injuries were. The dog seized me on the calf of the leg. It did not tear the trousers or

drawers, and did not make the leg bleed, but left several tooth marks, pulling up the skin, but not clearly tearing the capillaries. It also left a reddish scratch, over an inch long. To get the dog away I seized it by the mouth, and in so doing it snapped and took the skin off my thumb, tearing the capillaries a little more than the circumference of a pin's head, and tearing the skin about one-sixteenth of a square inch, but not tearing the red flesh. Then I sucked it for about one and a half or two minutes. In less than five minutes I applied nitrate of silver, and in less than seven minutes washed the entire hand in crude coal tar naphtha. I only washed my leg in soap and water. The dog seemed feeble, and I thought it did not seem to know what it was doing. I saw the dog on the other side of the street one minute before, and thought what a strange dog it seemed. The other man was bitten much worse on the naked hand, and treated some half hour after at the Infirmary. It is now nine months ago, and I think we are both well, and, I trust, out of danger. I should like to read your book, and thinking you might not know how difficult it is to get, I have taken the liberty of writing you.—Yours faithfully,

Warrington,
March 19th, 1888.

S. K.

TARDY CONVALESCENCE IN THE PUERPERAL STATE.

To the Editor of "The Provincial Medical Journal."

SIR,—I treat all cases of the kind described by Dr. Johnston with the *Liquor Ferri Perchlor. Fort.*, in from two to five minim doses. The blood is deficient in fibrin, as well as hæmoglobin; hence, alkalies are worse than useless, because they intensify the mischief by lessening fibrin. The only untoward effect occasionally observed is the development of colic in the baby, from the action of the steel on the mammary secretion. This can be prevented by the administration of small doses of ammonia and soda to the baby, during the time the mother is taking iron. A remark or two here on the use of ammoniated ergot may not be out of place. Although there can be no doubt that this preparation acts very rapidly in securing contraction of the uterus, in virtue, in all certainty, of the diffusibility of ammonia, there is, I think, a risk of inducing hæmorrhage in cases of collapse, because of the defibrinating action of that drug on the blood.—I am, Sir, yours faithfully,

March 19th, 1888.

C. R. ILLINGWORTH, M.D.

PROVIDENT DISPENSARIES.

To the Editor of "The Provincial Medical Journal."

SIR,—Your article upon the present state of the medical profession deserves great credit for the true light in which the laity try to obtain the services of medical men. Would it be legitimate for the respectable portion of medical practitioners to issue hand-bills in opposition to these so-called bogus "Provident Dispensaries," pointing out how absurd it is that the public should be so gulled, and thus entrust their lives in the hands of these cheap medicine vendors? I, for one, would be only too glad to open their eyes, and so expose the utter loss of life caused by such cheap quackery. In this part of London handbills are given in all directions, and posters placarded on walls, announcing that on the opening of such a dispensary, "advice and medicine" will be given free for the first week. Something should be done, for the public either will not or cannot find out how to obtain proper medical advice.—Yours obediently,

White Horse Street, Stepney, E.,
March, 1888.

M. CURSHAM CORNER.

NOTICES OF DEATHS, BIRTHS, AND MARRIAGES, occurring in the families of our subscribers will be inserted, free of charge, in the *Provincial Medical Journal* if sent, duly authenticated, to offices.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

Aids to Obstetrics. By Samuel Nall, B.A., M.D. Cantab., etc., etc. Third Edition, pp. 142. London: Baillière, Tindall & Cox.

Aids to Dental Surgery. By Arthur S. Underwood, M.R.C.S., L.O.S., pp. 100. London: Baillière, Tindall & Cox.

Laryngoscopy and Rhinoscopy, in the Diagnosis and Treatment of Diseases of the Throat and Nose. By Prosser James, M.D. Fifth Edition, enlarged and illustrated. London: Baillière, Tindall & Cox.

The "More Excellent Way" in the Practice of Medicine, pp. 45. By John Clemenson Day, M.D. Lond. London: R. Gould & Son.

Lectures to Practitioners on the Diseases Classified by the Registrar General as *Tabes Mesenterica*. By W. T. Gairdner, M.D., LL.D.

On the Pathology of Phthisis Pulmonalis. By Joseph Coates, M.D. With twenty-eight engravings on wood. London: Longman Green & Co.

ERRATUM.

Since going to press with the Biography of Dr. Bucknill, we find the statement that he has retired from practical work is an error.

Dr. Bucknill still practises as a Physician.

THE Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

MAY 1, 1888.

[No. 77.]

Our Portrait Gallery.

JOHN CHARLES BUCKNILL, M.D., F.R.C.P.,
F.R.S.

THE subject of our sketch has been one of the pioneers in lunacy reform, and has made for himself a reputation in a speciality which has been distinguished by the number of eminent men who have been associated with it. Though he has now retired from practical work, yet he has not lost his interest in that art to which his life has been devoted.

John Chas. Bucknill was born in 1817, at Market Bosworth, and educated at Rugby and Bosworth Schools. He received his medical education at University College, London, of which he is a Fellow, and has for many years past been a member of the council. In 1840 he graduated in honours in the University of London, being first in Surgery, and third in Medicine. In the College of Physicians of London he has been Censor, Councillor, and Lumleian Lecturer. In 1844 he was appointed the first Medical Superintendent of the Devon County Lunatic Asylum, an office which he held until 1862, when he was appointed Lord Chancellor's Medical Visitor of Lunatics, which office he held until 1876.

He is a Justice of the Peace for the county of Warwick, and a visitor of the County Asylum. In 1853 he originated—and afterwards edited for nine years—the *Journal of Mental Science*, and he is one of the original editors of *Brain*.

In 1877, as President, he delivered a remarkable address in the section of physiology, at the annual meeting of the British Medical Association, Manchester, in which he showed his broad views on the special branch of the profession in which he was himself engaged. "This occasion," he said, "seems opportune for speaking on a

subject of great and general importance to us as specialists—viz., whether the customary practise of our speciality does not frequently tend to impair our usefulness by limiting our field of observation, and narrowing our views of men and of society. . . . There can be no doubt that all special employment leads to narrowness of mind, and that the learned professions suffer from this most notably. This was indeed long ago pointed out by Archbishop Whately in his work on "Rhetoric," and there can be no doubt there is a legist's narrowness, a priest's narrowness, and a physician's narrowness." He told his audience how to get out of this, and insisted "upon the great need of the mental physician to breathe much of the pure air of rational life, for the sake both of himself and his patients. If there be one man more than another who ought to be a man of the world, it is the physician who has the care of the insane; for if he allows himself to become ignorant of the outside world, he will be able to make no comparison of the sane with the insane, and, therefore, liable to consider opinions and conduct morbid which are only strange." This address, short, learned, shrewd, of wide literary range, is an excellent sample of Dr. Bucknill's style.

He has published "Unsoundness of Mind in Relation to Criminal Acts" (Sugden Prize, 1857); "Manual of Psychological Medicine" (last half), 1858; "The Psychology of Shakspeare," 1859; "The Medical Knowledge of Shakspeare," 1860; "Notes on American Asylums," 1876; "Habitual Drunkards and Insane Drunkards," 1878; "Care of the Insane and their Legal Control," 1880; and also numerous pamphlets, lectures, and articles in journals on "Insanity" and allied subjects. In 1852 Dr. Bucknill, through the influence of the late Earl of Fortescue, obtained the permission of the Government that the 1st Devon and Exeter Volunteer Rifles should be embodied, and he was the first recruit of this the primary regiment of the New Volunteer Regiment.

Original Communications.

THREE CASES OF MALIGNANT DISEASE OF THE RECTUM IN WHICH COLOTOMY WAS PERFORMED.

By W. H. JALLAND, F.R.C.S. (EXAM.),

SURGEON TO THE YORK COUNTY HOSPITAL.

In cases of malignant disease of the rectum the treatment naturally resolves itself into two kinds—either curative by removal of the affected portion, or palliative. Unfortunately, in the cases I am recording, the hope of cure by means of excision of the rectum was quite out of the question. The disease in all the cases, involved far too large a surface of the rectum and contiguous parts for that operation to be entertained at all, and the only course left to be adopted was the palliative one, in hope, by so doing, to prolong life somewhat, and to make the remainder of life more comfortable. In the first two cases this has been so in a marked degree. Not only has the pain been relieved by colotomy, but both the cases are now going about fairly comfortable, and enabled to follow their usual avocations with apparently little trouble from the original disease or the artificial anus. The third case, unfortunately, was not not so successful. I only performed the operation in this case to relieve the almost impending complete obstruction which threatened, and although this result was obtained, the poor man sank in a few weeks from exhaustion due to the spreading of the disease, although he was quite well from the operation. All the cases were under my care in the York County Hospital, and the notes were taken by Mr. E. F. Morris, House Surgeon.

Malignant Disease of Rectum (? Epithelioma)—Colotomy—Recovery.—Samuel C—, æt. seventy, labourer, residing at Sutton, under White Horse Cliff, was admitted into the York County Hospital on May 30th, 1887. Patient has been ill now about eighteen months. His attention was first drawn to the disease by the loss of a great deal of blood when he had an evacuation, also by having great pain in his head. The loss of blood becoming greater, and its effect more weakening, he consulted a medical man. He suffered from constipation. He was not examined by a medical man till fourteen days before his admission. Family history, good; previous history, negative. On admission, a rectal examination was made, when it was found that there was a large, hard, irregular mass of new growth, involving the whole of the calibre of the rectum, which was strictured so that the finger could scarcely pass through, and the upper limit could not be reached; it was adherent to the prostate gland, and extended downwards almost to the anus. The examination caused a great deal of pain. The man suffered from constipation, alternating with diarrhoea, and there was always a good deal of blood passed with the motions. He had not lost much flesh, but was evidently a good deal pulled down by the great pain he suffered upon defecation and loss of blood. As it was quite impossible to remove the whole of the disease by excising the rectum, Mr. Jalland decided to perform colotomy.

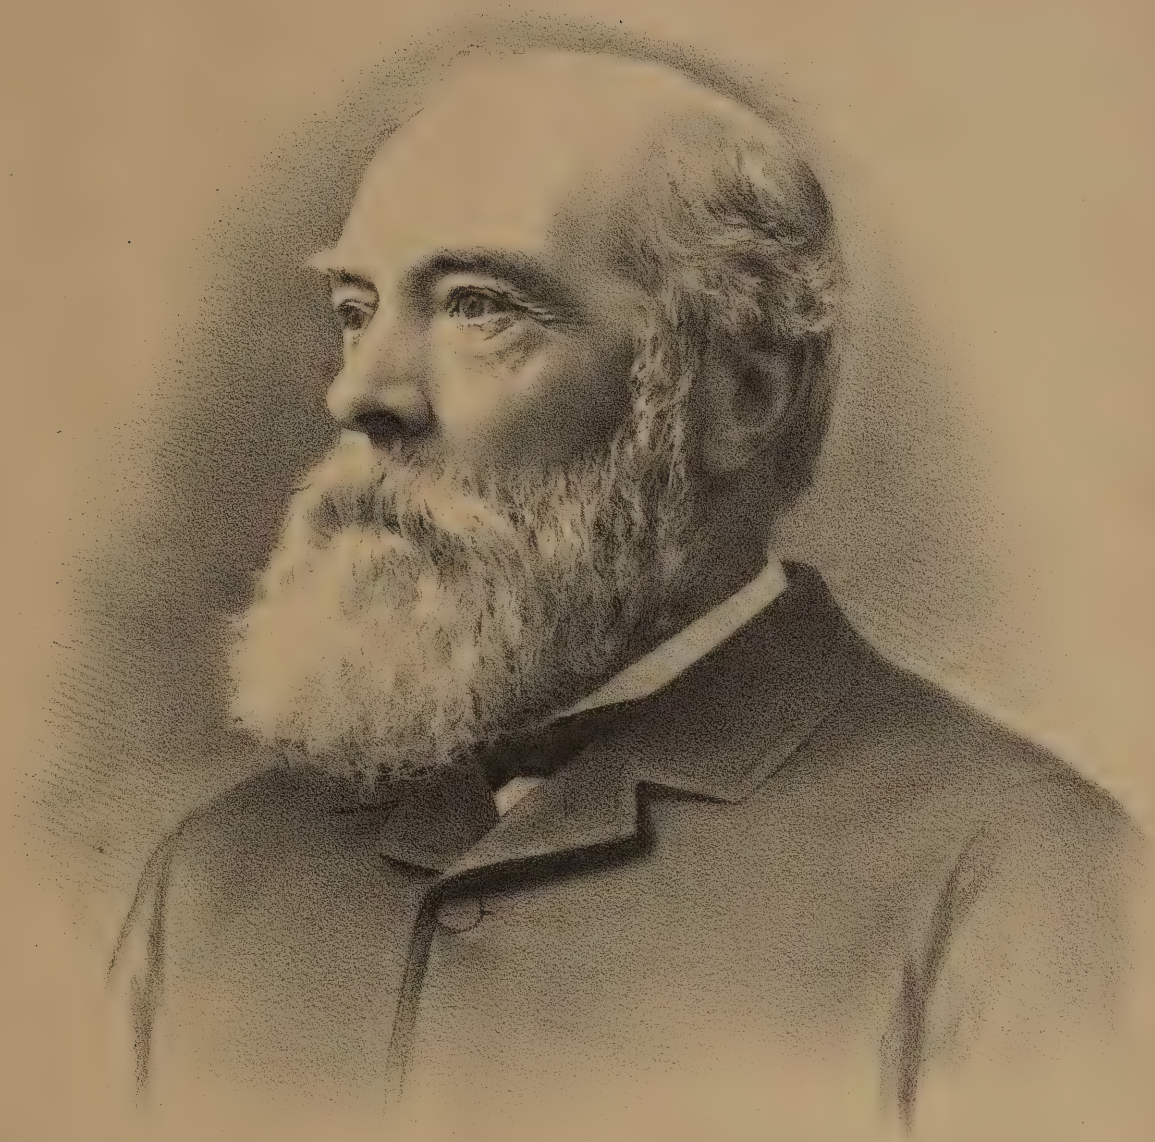

June 7th.—Ether being given, Mr. Jalland performed left lumbar colotomy. The oblique incision was adopted. The bowel, after slight difficulty, was discovered quite empty. It was raised, stitched to the skin, but not opened, and the operation was performed under the carbolic spray, and dressed with iodoform and salicylic wool.—June 8th.

Patient has passed a good night, and seems quite comfortable.—9th. This morning the dressings were removed, and Mr. Jalland made an opening into the bowel.—12th. As very little fæces had passed through the wound, some castor oil was ordered, and a piece of oil lint put into the opening in the bowel.—15th. A good evacuation through the wound.—17th. All the stitches removed; fæces pass through the wound copiously.—23rd. Patient doing very well; wound nearly healed; fæces pass freely through the artificial anus.—July 11th. Patient left the hospital to-day, much improved in health, and with a good artificial anus.—March, 1888. Patient has been frequently heard of since he left the hospital. He is now following his usual employment, which he is able to do with very little discomfort, and almost free from pain.

Malignant Disease of Rectum (? Epithelioma)—Colotomy—Recovery.—Eliz. A—, æt. about sixty-five, residing in York, was admitted into the York County Hospital on June 27th, 1887. Patient has been attending the outpatient department, under Mr. Shann, who advised her admission. She has been ill for twelve months. First noticed great pain in back, followed by diarrhoea, consisting of blood and mucus, and she compares the motion to "rotten liver." Nothing was noticed at the anus until fourteen days ago, when a sinus formed at the posterior part. Family history, negative; previous history, good. On examining the rectum, there was found an irregular mass encircling the gut within the reach of the finger, which so constricted it that it only admitted the tip. It was adherent to the posterior wall of the vagina, but had not perforated it. It extends down to the anus. Many sinuses round the latter. There was a constant discharge of blood and mucus from the anus, and great pain when any fæces were passed.

June 20th.—Ether being given, to-day Mr. Jalland performed left lumbar colotomy, the oblique incision being adopted. The bowel was found without any difficulty, and opened at once.—30th. Patient doing very well; fæces passing freely through the wound, very little by the stricture.—July 10th. Patient has been doing very well, except some slight increase of temperature, for which at present no cause can be found.—29th. To-day an abscess was found at the lower margin of wound, occasioning the rise of temperature; this was opened.—August 8th. Patient now quite well, except that her mental condition was not quite satisfactory.—15th. Was discharged to-day, with very good artificial anus.—March, 1888. Has been seen frequently since her discharge. The original disease seems to be making very slow progress. She has very little inconvenience from the artificial anus, and is able to follow her usual household duties.

Cancer of Rectum—Colotomy.—Robert A—, æt. sixty-two, was admitted into the York County Hospital on November 22nd, 1887. Complained of losing much blood by the rectum. He was admitted into the medical wards, under Dr. Turner, but finding that the hæmorrhage proceeded from some growth round and immediately within the rectum, he was sent to the surgical side of the house. Patient, an extremely cachectic-looking man, gives the following history:—About seven months ago, began to suffer from constipation. This continued for a month or so, the stools being at times somewhat tinged with blood. At the end of a month, diarrhoea set in, accompanied by great tenesmus, with much hæmorrhage. He began to lose flesh rapidly, lost colour, and was unable to sleep, so at last sought admission into the hospital. On admission,

Very truly yours

B. Smith

patient is extremely cachectic, very feeble, and emaciated, complaining most of pain and tenesmus on defecating, with much hæmorrhage. On examination, as far as the finger could reach was one hard infiltrated mass—rough, extremely vascular, and painful to the touch. At the upper portion the opening was very small, barely admitting the tip of the finger. He was advised, at a consultation held by Mr. Jalland and Mr. Hewitson, to undergo an operation—colotomy, and he consented. There was also a large mass of enlarged glands in the groin, evidently secondary infiltration.

November 27th.—Ether being given, Mr. Jalland made the usual oblique incisions in the left loin, operating under the carbolic spray. After division of the usual structures, the bowel was easily found. It was stitched to the sides of the wound, but not opened; dressed with salicylic wool and iodoform.—27th. Patient has passed a comfortable time, with the exception of some pain at the seat of disease, relieved by a small morphia injection. To-day Mr. Jalland opened the bowel with a tenotomy knife.—30th. There has been some escape of fæces to-day, and patient expresses himself as being more comfortable.—December 3rd. The opening into the bowel having closed a little, was enlarged, with much relief to the patient. Dose of castor oil ordered, after which there was a free discharge of fæces through the wound.—10th. Wound has now healed; still hæmorrhage from the anus, fæces escaping through artificial opening.—17th. Though the wound has healed, patient is very feeble, and does not rally, although he takes plenty of nourishment.—22nd. Patient rapidly failing; wound quite healed.—27th. Died to-day, simply from asthenia.

ON CANCER.¹

BY FORDYCE BARKER, M.D., ETC., NEW YORK.

THE opening of a new Hospital in this city, the first in this country and the second only in the world, devoted exclusively to the treatment of cancer, is an event of such importance that I greatly regret that the selection of a person to give the address had not fallen upon one more competent to do justice to the occasion. But some considerations have been forced upon me, which seem to make it an imperative duty to accept the position and throw myself on your kind indulgence.

One inducement which had its weight on my mind is the fact that I do not profess to be a surgeon, and as the wonderful progress made within the past decade, in the successful cure of many cases of cancer which before would have been left to die a miserable death, has been in the domain of surgery and the result of surgical proceedings, I can speak of these without any imputation of self-laudation.

My purpose is simply to show the necessity for and the usefulness of such a Hospital—to impart some knowledge of the nature of this terrible disease, cases of which will seek relief and cure within these walls,—and to correct some popular errors in regard to it which seem to be almost universal, and which the profession well know have caused an incalculable amount of unnecessary misery and unhappiness in the world. It is to be confidently hoped that the good which this hospital will eventually accomplish in the relief of unhappiness and suffering will be represented only in a minor degree by its future inmates, but will extend to many thousands who will never be within its walls.

¹ An address delivered at the opening of the New Cancer Hospital, New York, December 6th, 1887.

As preliminary to what I am about to say, I may be permitted to define some words which are in general use by the public in a sense quite different from their professional use. The word tumour when applied to any abnormal enlargement in any part of the system is one which carries terror to the minds of most patients, who often consult their physician because of an avowed apprehension that they have a tumour.

The word tumour is nearly but not exactly identical with the word swelling, and carries to the professional mind no significance as necessarily implying danger to life. We speak of glandular tumours, fatty, cellular, or fibrous tumours, as innocent, or benign, meaning thereby that they are purely local growths, having no tendency to extension by formation of other growths, and that if removed they are gone forever. But we also have what are called malignant tumours, which involve a destructive degeneration and gradual invasion of adjacent tissue, and which may finally infect the general system and destroy life.

Cancer, using the term in a general sense, is a typical form of malignant tumour. It is probable that this was first observed and studied as an external disease. The name is said to have been given to this affection by Galen, who lived in Rome in the latter part of the second century, a physician of great eminence, and one of the most accomplished and learned men of his age. From a fancied resemblance of the appearance of the disease as it extends itself into adjacent healthy tissues to the claws of a crab, he gave it the Latin name of crab, namely cancer. Since his day the name has been universally adopted both by the medical profession and the public, and is popularly applied to all forms of the so-called malignant growths, such as scirrhus or hard cancer, encephaloid or brain-like cancer, epithelioma, the rapidly growing, infecting, and recurrent forms of sarcoma, and other varieties, which may differ much in structure, and in their clinical features.

The malignancy which is the common characteristic of all, justifies the long-continued popular usage of the term cancer to cover all these diseases, and all come within the province of this hospital to treat. I will briefly refer to some of the peculiarities of this group of diseases which distinguish them from all others. They have for some years been gradually increasing in frequency and causing a larger proportion of deaths in those nations which are the most advanced in civilisation.

In the Forty-first Annual Report of the Registrar-General of England, published in 1880, it was asserted that the number of deaths from cancer was 5,218 in 1851, and 12,664 in 1878, but as the population had largely increased in this period, the increase in frequency will be more distinctly appreciated by the following quotation from this report: "The average annual mortality (from cancer) during the five years 1850-4 was 304 in one million living. In the five years 1870-4 it was 443, while in the year 1878 it was 512."

In New York City, the proportion of deaths from cancer in 1875 was 400 to the million. In 1885 it was 530 to the million. According to the Reports on Vital Statistics of the Census of the United States of 1880, the proportion of deaths from cancer to the total number of deaths reported from known causes was 36.68 to 1,000.

Cancer is a disease of advanced age. It is found in all ages but in very unequal proportions. In 8,193 cases the proportion of deaths under 5 years of age was 15.95 per 1,000, while from 5 to 10 it is only 2.82 per 1,000, and from 10 to 15 1.60 per 1,000. From the age of 15 the

proportion gradually rises in each quinquennium, until between the ages of 50 and 55 it reaches 130.18 per 1000. After this period the proportion gradually diminishes as the population of those living after this period of life decrease. Mr. Jonathan Hutchinson, of London, whose opinion on all questions of pathology is considered authority by the profession in all parts of the learned world, in the most able discussion which has ever been held on this subject, that before the Pathological and Clinical Society of Glasgow in 1886, said: "Of the causes which underlie the proclivity to cancer, and which render some races and some families more prone than others, we as yet know but little. What little we do know would lead us to believe that it has nothing to do with diet or with climate. The herbivorous animals are liable to it as well as the carnivorous, and so far as I know it prevails in all parts of the world where the conditions are favourable to longevity. Wherever, from whatever cause, they are not so, there cancer becomes relatively infrequent. It is almost unknown in those of our domestic animals which are used for food, for the simple reason that we never let them grow old, while in dogs, cats, horses, and asses it is common."

Dr. Billings says: "The increase of mortality from cancer with advancing age may be explained either on the theory that the cause of cancer becomes more potential in advanced age at the period of physiological decay, or on the theory that the predisposition to cancer belongs to the strongest and longest lived." The fact is settled beyond question, that in those populations where but few reach old age, cancer is proportionally rare.

There are some curious and interesting facts in regard to the geographical distribution of cancer, which science as yet does not satisfactorily explain.

The last census of the United States demonstrates that this disease is especially prevalent in the New England States and on the Southern Pacific coast, that it is prevalent in New York, Pennsylvania, Ohio, and in the interior of Michigan and the southern part of Wisconsin. That it is least prevalent upon the Mississippi and in the South, and that the proportions are generally lower in the coast regions than in the interior. An examination of the reports of death from cancer in England and Wales made by Dr. Havil and leads him to conclusions quite in accord with those derived from our own census. Both banks of the Tweed near Berwick, and of the Tyne at Newcastle, some parts of Yorkshire, and the whole of the beautiful lake district are fertile beds of cancer. The Isle of Wight is all but free from this disease, while it is common in Brighton, Folkestone, Dover, Ramsgate, and Margate. Statistics also demonstrate, as other facts have seemed to prove, that density of population, poor living, and laborious toil have very little to do with the development and appearance of cancer. Thus in London, in which, as a whole, cancer is very prevalent, the parish of St Luke's, the neighbourhood of Bishopgate-street, crowded Bethnal Green, the Isle of Dogs, Rotherhithe, and Bermondsey, are almost exempt from this disease, but in the respectable parts of the metropolis, about the Marylebone-road, Regent's Park, and Primrose-hill it is exceptionally frequent. In Liverpool, which has a large mortality from other causes of death, the percentage of deaths from cancer was very small. In the future it may be discovered that in the localities where the prevalence of this disease is most frequent, they have certain characteristics in common which science may overcome and thus notably diminish this tendency in such localities.

In the Report on the Vital Statistics, of the United States of the Tenth Census in 1886, it is remarked that the peculiarities of the differences in mortality from cancer in different localities may be in part explained by differences in the population of these localities as regards race and age. It is a disease which is much less frequent in the coloured than in the white race, hence the mortality from it is greater in the North than in the South. It causes the greatest proportion of deaths where there are the greatest proportion of people of advanced age,—that is to say, in the New England States. Hence in any given locality, a large proportion of deaths from cancer indicates, to a certain extent, that the locality is a healthful and a long-settled one and has a large proportion of inhabitants of an advanced age.

Cancer is not a disease due to misery, to poverty, to bad sanitary surroundings, to ignorance, or bad habits. On the contrary, it is a disease of the most highly civilized, the most cultured, the wealthy, and of localities which are the most salubrious. One of the characteristics of cancer is that, unless the brain is involved, it leaves intellectual power and force unimpaired. Nay, it seems that in some cases it almost increases these qualities.

No pathetic incident is more indelibly stamped on my memory than a visit made to a victim of this disease, whom I found, as I often had before, seated at his writing-table, his drawn, pallid face expressing fatigue and suffering, but still more expressive of will force and a remarkable power of endurance.

"Excuse me," he said, as I entered the room, "until I finish a paragraph that I have just begun." After a few moments he laid down his pen, saying with a sad gleam of satisfaction: "There, since your visit yesterday I have written eight pages."

After the commencement of his painful illness, stimulated by the hope of overcoming reverses and leaving his family in circumstances to which their former position entitled them, he succeeded in accomplishing a larger amount of work, and receiving a greater pecuniary reward for it, than in the history of the world was ever before acquired for literary work in so short a period of time.

Census reports are to most persons uninteresting, and the value of the two large volumes of the last census, which relate to the vital statistics of this country, can be appreciated by but few persons; nevertheless, I wish to call your attention especially to the importance of these books, and to the remarks in which Dr. J. S. Billings, of the United States Army, under whose direction they were compiled, sums up the conclusions which may be drawn from them, and points out the way in which such statistics should be extended, improved and made reliable as a means of increasing our knowledge of the causes of pain and death, and the means of destroying or of diminishing these causes.

The belief has been almost universal, both with the profession and the public, until within a comparatively recent period, that cancer has generally an hereditary origin. It is probable that no doctrine in regard to the cause of disease has given rise to so much and so causeless misery and unhappiness in the world as this. In those who have some symptoms which they suspect to indicate the beginning of this disease, suspicion becomes a conviction, if any relative of a former generation has died of cancer. They may almost be said to begin the pangs of a moral death long before it is demonstrable that physical death is

inevitable from this cause. If the patients have any family history of this disease, and are suffering from any acute or chronic affection attended with symptoms which they have heard exist in cancer, the affect of this conviction is not only depressing, but dangerously complicates conditions which otherwise might result in recovery. I have personally known many illustrations of the truth of both of my two last assertions. Again, I have more than once been asked in those pathetic tones which tell of heart-breaking anxiety: "Are my children or is my daughter doomed to suffer as I now do?" The answer given in no equivocal words is: "The probability of such a doom for any descendant of yours is extremely small." In all the statistics which I have been able to collect, where the antecedent family history seemed to be trustworthy, I have found that the proportion of those who have had cancer, in whom some relative of a former generation is reported to have had some form of malignant disease, to be only 13.65 per cent. On the other hand, in one family which has in the present generation the largest number of victims that I have ever personally known, I have authoritative proof for asserting that no development of any form of malignant disease has ever existed in three previous generations, including collateral branches.

Before a professional audience I could give a list of names which would be regarded as conclusive as to present belief of the profession on this point. More than a quarter of a century ago, Mr. Jonathan Hutchison, whose opinions carry the greatest weight, expressed his disbelief in hereditary origin as an effective cause. Recently, that is during the past year, in a notable and most able discussion of this subject, he said: "It is utterly useless to employ such a term as hereditary transmission of cancer in such a sense as we speak of the transmission of some other diseases.

A proclivity to the disease may result from the conjunction of certain parentage, but it cannot be said to be inherited from ancestors in whom it did not exist. We may speak of cancer being hereditary as we speak of delirium tremens as hereditary, but in neither case is this transmission of the disease. Parents cannot transmit to children disease which has no existence in their own system previous to the birth of the children, and thus it is absurd to say that a daughter has inherited the disease which her mother first developed twenty-five years after the birth of the daughter.

A cancer bacillus is as yet unknown in science, and the most recent investigations have failed to find any. But I observe that Sir James Paget, in a lecture delivered on the 11th of November, expresses the belief that micro-parasites or substances produced by them will some day be found in essential relation with cancer and cancerous diseases. But as yet there are no ascertained facts which support this belief.

In a paper read before the Academy of Medicine in 1870, I then avowed the opinion that cancer could not be regarded as an hereditary disease, but that an hereditary tendency to it often exists in those whose ancestry has been wholly exempt from it. In such it is probably developed by some local exciting causes.

Cancer was regarded by Abernethy (a great authority in pathology and surgery during the early part of the present century) as being simply the local manifestation of a constitutional disease. Within the past few years a large number of the most eminent pathologists have become

adherents to the doctrine that it is primarily a local disease, and that the constitutional affection is a secondary result.

This is not the time or place to review the various able arguments which have been urged in favour of one or the other view, but it is a point of great importance as effecting the question of the curability of the disease. In the first place, no medicine has yet been discovered which acts specifically in retarding or curing the disease, as quinine and mercury and others do in certain specific diseases. No man has the moral right to administer any drug without some well defined view of the end which he wishes to accomplish and a well grounded belief that the drug he selects will probably effect this result. But in cancer we do not know what primary changes are necessary in either tissue or function to prolong life or cure the disease. Even if we did know this, no drug has yet been found which experience has proved will effect these changes. So it may be positively asserted that no case of cancer has ever been proved to have been cured by medical treatment. But many cases have been arrested for months and years by surgical treatment; and as after three years it is generally believed that the probability of recurrence is very slight, we have the right to say that many cases have been absolutely cured by total removal of the disease tissues.

I think sufficient facts have been accumulated, especially within the past ten years, to justify the following assertions:—

Total removal of the whole diseased growth, when it is found as a distinctly limited affection, the lymphatic glands not being involved, it is highly probable will be followed by a cure.

If the disease has involved the lymphatic vessels and glands, the chances of cure are materially diminished; but in many cases an operation has proved to be of great service in relieving suffering and prolonging life for months and in some cases from one or two or three years.

After the local disease has existed a sufficient length of time to contaminate the blood and infect the general system, a cure by an operation or by any other method is absolutely hopeless. Great progress has been made in successful surgery within the past few years by a resort to the operation at the earliest possible period, that is, so soon as the existence of the disease can be determined.

The most recent, and probably the most authoritative writer on this subject, Mr. Butlin, of London, asserts that every week of delay increases the danger of the contraction of various adhesions, of affections of the secondary glands, and of the formation of secondary growths. But duration alone is not a conclusive argument against the success of an operation; for, as the same author adds: "When long duration of a malignant tumour is associated with a very slow progress, small size, absence of serious adhesions, absence of affection of the neighbouring lymphatic glands and of secondary growths, so much the more favourable is the prospect of permanent relief from operation for its removal." The question of the locality of the growth is one of great importance in forming a decision as to the necessity and probable success of removal, and will always be carefully and conscientiously weighed before a decision is made. These malignant growths may appear in any tissue of the body, external and internal, and eminent surgeons of this city, as elsewhere, have removed them with all the success anticipated from muscles, bones, lymphatic glands, the eye, the face, the lower lip, the tongue, the breast, and other external organs.

If this were a fitting opportunity, and time would permit, I am sure all present would be interested in hearing an account of such as I have a personal knowledge of, either from my own observation, or from a knowledge derived directly from the operators. But such details would be inappropriate on the present occasion, and I am compelled to deny myself the pleasure of paying a just tribute to the skill and sound judgment of surgeons that we have in our city.

Dr. S. W. Gross, of Philadelphia, asserts: "The convictions are steadily gaining ground that this disease in the breast is primarily a local affection, and not a constitutional one, and that these views are supported by many of the most eminent men living—pathologists such as Virchow, of Berlin; Bilroth, of Vienna; Fersche, of Breslau; Esmarch, of Kiel; Nussbaum, of Munich; Volkman, of Halle; Erichsen, Hutchison, Gull, Simon, Bryant, Green, and others, of London; and the late Dr. Gross, and Parker, Peters, Moore, Richardson, and others, in the United States, have shown by the statistics of their practice, and that of others, the usefulness and success of the surgical removal of the disease."

But as I have said before, removal of the disease by operation is not restricted to external organs, for many operations for removal of internal organs have been performed with all the success that could be anticipated, although it must be added there have been many failures. On November 14th, three weeks ago, I was present when one of the Medical Board of this Hospital performed one of the most difficult operations ever attempted in surgery—viz., the entire removal of the most important internal organ. I had previously seen the patient, and concurred in the opinion that the operation was imperatively necessary, and that it offered a fair promise of success. I may add that the opinion of the operator and myself was given independently, each without the knowledge of the other. The patient, as I have learned within a few days, has had no unfavourable symptoms which have retarded her convalescence. It is possible that she may hereafter escape any return of the disease. It is certain that her life has been prolonged, and that she has been saved from months or perhaps years of suffering, which would have soon ended her days. A fair number of cases have been reported in which such results have been attained. And yet so late as fifteen years ago, any proposal to attempt such an operation would have been condemned by the universal sentiment of the profession; and if it had been attempted and resulted in failure, the public would have denounced the operator as a reckless, unscrupulous butcher, who had no conscience as regards the result to his patient, but simply sought personal glory in the éclat of having performed a wonderful operation. All of us have before heard such language applied to surgeons.

The case which now commands the most universal sympathy and interest in all nations of the world is that of the Crown Prince of Prussia. It is an unparalleled event in history that three men, two of whom had been at the head of the government of their respective nations, and the third, whose probable inheritance was an empire, should each have been victims to malignant disease in contiguous localities, differing only in some minor details, at the same period in the world's history. In the case of President Grant, the locality of the malignant growth was such, that it was decided by the most competent authority, that from the

beginning a successful removal by surgery was not practicable, as the danger from such an attempt would be greater than the probability of any benefit. During the illness of General Grant, I received a letter from the brother-in-law of Don Ferdinand, ex-King of Portugal, and his attending surgeon, detailing the history and description of the case of the ex-King, in whom malignant disease had also appeared in the mouth, very near to but not exactly in the same site. From the description given the conviction was irresistible to my mind that it would be impossible, by any surgical procedure, to remove the whole of the disease tissue, and that any attempt of the kind would be attended with such danger as might be followed by immediate death, and would undoubtedly shorten the duration of his life. His death followed within a few months that of our honoured ex-President. As regards the probable future of the case of the Crown Prince, none but those able men who are in attendance upon him, and who must have a knowledge of many details which are essential elements, but which it is impossible to explain to the world, are competent to form or express any opinion of value. In general terms, I may say that his general health is reported to be very good; that the progress of the disease appears to be slow as compared with some cases I have seen, and I may add, if it be decided by his medical advisers that partial or entire excision of the larynx should be performed, we have abundant evidence that in a certain number of cases both of these operations have prolonged life to a period when the probability of recurrence is very small. In some cases entire excision has saved life for a length of time that gives great encouragement for hoping that the ravages of this terrible disease have been arrested. Two such happy results have been reported in this country and several abroad. Dr. Roswell Park, of Buffalo, in June, 1885, removed the entire larynx on account of the existence of this disease in a patient who was himself a medical man. In a letter dated November 22nd, he writes to me: "The doctor has a number of relatives in Buffalo, and as I frequently see one or more of them, I am kept pretty well informed as to his condition. My latest news is so recent as last week, and to the effect that he is as well as ever."

It must be obvious that all new and important operations are followed by a progressive success in their results, as the methods of operating are improved in their details, and as the after-treatment necessary becomes better known. The percentage of successful results increases in a ratio in proportion to the experience acquired by the increasing number of the operations. Indeed, I may add that it is my conviction that the progressive number of cures of this terrible curse to humanity is in a more rapid ratio than the progressive increase of the frequency of the disease.

Need I say more, in the light of the past, to point out what may be hoped for in the future from such a hospital as this, under the devoted zeal of the active staff, whose ability, competency, and faithfulness to their duty have already been demonstrated in other positions. Can any one have a doubt as to the probable service to humanity which will result from the careful observation and study by such competent men of details that can never be acquired except in a large hospital?

I question whether any, even the most sanguine, has more than a feeble conception of the benefit to the victims of the disease to be here treated, and to thousands of others, that will result from the opening of this Hospital.

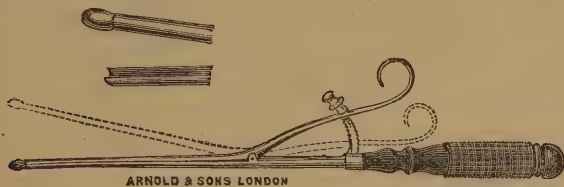

ON THE TREATMENT OF OBSTRUCTIVE
DYSMENORRHOEA AND STERILITY.¹

BY THOS. MORE MADDEN, M.D., F.R.C.S.E.,

OBSTETRIC PHYSICIAN, MATER MISERICORDIÆ HOSPITAL, DUBLIN; PRESIDENT-ELECT, OBSTETRIC SECTION, BRITISH MEDICAL ASSOCIATION; EX-PRESIDENT, OBSTETRIC SECTION, ROYAL ACADEMY OF MEDICINE IN IRELAND; PHYSICIAN, HOSPITAL FOR SICK CHILDREN; CONSULTANT, NATIONAL LYING-IN HOSPITAL; FORMERLY VICE-PRESIDENT, BRITISH GYNÆCOLOGICAL SOCIETY; AND EXAMINER IN OBSTETRICS AND GYNÆCOLOGY, QUEEN'S UNIVERSITY, ETC.

(Continued from page 167.)

Operative Treatment of Cervical Stenosis.—As the method I employ in these cases differs in some respects from that generally adopted, I may be here permitted to refer briefly to its details. I may observe that during the past eleven years I have operated on several hundred cases of stenosis, and within the last year I thus successfully treated in my hospital very nearly a hundred such cases, in many of which I had the assistance of Dr. Duke, Obstetric Physician to Stevens' Hospital.

In the first place, I would advise that this operation should be undertaken about a week after the termination of the last painful menstrual period, and that it should be preceded by daily hot water syringing for some days. To proceed with any comfort to ourselves or advantage to our patient, she should be placed under ether or mythelene, and adjusted in the ordinary left lateral semiprone position, on a proper gynæcological couch or table. Then, the cervix being exposed by the duck-bill speculum, the anterior lip is seized by a strong volsellum, and drawn down by an assistant as close to the vulva as possible, where it is to be retained. Next the sound should be passed to ascertain the position of the uterus, as well as the immediate permeability of the canal. Then the metrotome (and I myself much prefer Simpson's original instrument to any of its modifications) should be introduced well into the uterine cavity, and, being expanded to whatever extent may be deemed necessary in each case, should be withdrawn so as to divide the cervix freely in a transverse direction from the os internum to the outer orifice of the passage. It should be again introduced, and the same procedure repeated downwards, and again in an antero-posterior direction. The uterine cavity should now be syringed out with hot water so as to wash away all clots and arrest any hæmorrhage; then I introduce the dilator already described, and, expanding this to its full extent, I allow it to remain for a few moments, and then withdraw the instrument, with blades apart, so as to tear asunder and distend the cut surfaces until I can pass my index into the uterine cavity. In this way any probability of either hæmorrhage or of subsequent reunion of the divided parts is effectually provided against. Lastly, I introduce a tampon of Lawton's cotton, saturated in glycerine of carbolic acid, which is left *in situ* for some days, so as to fill and distend the passage from the uterine cavity to the os externum. The introduction of this may be found by no means an easy matter by the uninitiated,

and can best be effected by the employment of the sliding repositior.

After the operation the patient must be kept in bed on low diet, and syringed daily with hot water for eight or ten days, any pain being meanwhile treated by opiates and poultices. After this period a flexible tube or uterine stem pessary is introduced, which should be worn for another month, and then, and not sooner, the patient may resume marital life with a fair possibility of subsequent impregnation, and almost certainty of immunity from recurrence of dysmenorrhœa.

With regard to the results of this operation, my experience has been most satisfactory in the curative treatment of a large proportion of the cases of sterility and obstructive dysmenorrhœa that have come under my observation. This result I ascribe mainly to the thoroughness with which I carry out the dilatation and disruption of the contracted passage in the cases referred to. And as I have been reproached by some more timid practitioners with what they regard as the rashness or boldness of my practice in this respect, I may here venture to add that when cautiously, albeit boldly, carried out, in appropriate cases and by expert hands, no ill results need attend the operation in question, and I myself have had no such reason to regret its performance. In only two cases have I seen any serious hæmorrhage after it. Nor have I found it necessary to plug the vagina in such cases, as I have seen done by some practitioners, to the great discomfort of the patient. In very few instances have any inflammatory symptoms or cellulitis followed its performance, and in these cases the operation had already been performed by other gynæcologists previously.

Vaginismus as a cause of Sterility.—Besides cervical stenosis there are other causes of sterility which must also be considered in this connection. Of these, one of the most frequent and most important is vaginismus. As, however, I have discussed the pathology and treatment of this condition in a previous paper, I need here only briefly refer to those points which bear most directly on the subject of the present communication.

Excessive sensibility of the vaginal orifice and adjacent parts, more especially when associated with such spasmodic contraction of the sphincter vaginæ as to form an impediment to marital intercourse, or dyspareunia, occasionally becomes a matter of considerable gynæcological interest in connection with the treatment of sterility. In such cases the hyperæsthetic condition of the vaginal outlet is evinced even on the slightest attempt at local examination, and is most marked about the meatus urinarius, and in the vicinity of the orifice of the vulvo-vaginal glands and fourchette, whence the hymen, if existent, projects upwards.

With regard to the pathology of vaginismus, there are almost as many divergent views as there have been writers on the subject. For my own part I think the most rational explanation of these symptoms may be found in the hysterical temperament of the majority of those thus affected, although in some cases there is also present an abnormal condition of the pudic nerve, one branch of which runs along with the artery to the clitoris, whilst the other, or superficial perineal nerve, is distributed to the perinæum and labia, in which its terminal branches ratify freely. This fact in the ætiology of the disease is one the practical importance of which will be seen in connection with the treatment of vaginismus.

Treatment.—It was long since said in reference to this complaint by Dr. Marion Sims, that there is "no disease

capable of producing so much unhappiness to both parties of the marriage contract." I may here add from experience, that in many instances it may be found utterly impossible to deal satisfactorily with extreme cases of this kind by any of the ordinary plans of treatment heretofore generally recommended. As a rule, in the treatment of such cases very undue importance is given to local operative measures, whilst the constitutional treatment which is invariably necessary in all instances of well-marked vaginismus is too generally neglected. For whilst excision of the hymen, division of the pudic nerve, destruction of erythematous and serpiginous patches, dissections out of neuromata, etc., may each be indispensable in certain cases, in quite as many they are unnecessary. And, from my own clinical observation I can vouch for the possibility in some cases of relieving the most intense dyspareunia resulting from this cause, so as to enable the patient to fulfil all her duties as a wife and eventually as a mother, without any operation beyond the forcible mechanical expansion of the vaginal canal. Before resorting even to this expedient we should, in the first place, employ the sedative treatment, local and general, which is indicated in all other nervous or hysterical disorders, and which, as I believe, is essential in nine-tenths of the cases of vaginismus that come before us, whilst in only one-tenth of them is any surgical or operative measure necessary.

Amongst the topical palliative remedies that may, conjointly with the constitutional nerve sedatives just referred to, be employed in these cases are warm baths and vaginal irrigations, local application of solution of hydrochlorate of cocain or of glycerine of carbolic acid, or the introduction of suppositories of cocain and belladonna. When such palliative measures have been fairly tried without advantage we may then resort to mechanical dilatation of the vaginal orifice and stretching of the pudic nerve. For this purpose, having first fully etherised the patient, a large-size Graily-Hewitt bivalve speculum should be introduced and expanded to its fullest extent. Then a tampon of absorbent cotton large enough to fill the speculum should be soaked in glycerine and passed up to the cervix, its lower end projecting through the external opening of the instrument. This, still fully expanded, should then be forcibly drawn out, leaving the central tampon behind in the vagina. It need hardly be observed that this procedure occasions severe pain. At the same time, however, it as certainly tears through some of the superficial submucous muscular fibres of the affected part, as well as effectually stretches the terminal vaginal branches of the pudic nerve, and thus affords a generally efficient and safe method of overcoming the spasmodic contraction with which we have to deal in cases of vaginismus. Any subsequent contraction or hæmorrhage that may follow this procedure is sufficiently met by the tampon, which may be retained for at least twenty-four hours.

In some cases, however, this method of treatment does not suffice, and we must then resort to either Emmet's or to Sims's operation for vaginismus. In some instances I have found the hæmorrhage following these operations sufficiently serious, and in one of these I had to thank our Hon. Secretary, who was called in in my absence, for the arrest of a very alarming loss of blood, occurring some hours after the operation, in the case of a young lady on whom I performed Sims's operation.

It should here be observed that even in cases of vaginismus so extreme as to effectually prevent complete marital intercourse, the disease is not necessarily an absolute

barrier to impregnation. In one instance of this kind that came under my observation some years ago, so extreme was the local hyperæsthesia as not only to preclude the probability of complete cohabitation, but also to prevent the patient's submitting to any local treatment for the relief of the morbid condition. Nevertheless conception occurred, and I subsequently was called in to deliver her at full term, and in doing so was obliged to incise the still-unruptured hymen, by which delivery was obstructed.

Obstructive Dysmenorrhœa and Sterility from Vaginal Occlusion.—Amongst the causes of the morbid conditions under consideration some reference must be here made to occlusion of the vaginal passage whether by congenital malformations, or, as more frequently met with in gynecological practice, from cicatricial adhesions the result of disease or accident. With regard to the latter, although I have met with them in some instances, fortunately, however, clinical experience of retained menstruation, dyspareunia, and impeded delivery consequent on *post-partum* adhesions of the vaginal walls is fortunately more limited than must have been the case in the practice of our professional predecessors, in those good old days when the second stage of labour was allowed to run on until the vital powers were all but completely exhausted, before instrumental assistance was afforded in cases of difficult parturition. Nevertheless, as I have already observed, such cases are still occasionally met with.

Of somewhat greater frequency in the causation of this condition in modern practice is the opposite error. In other words, the integrity of the vaginal canal is now much more likely to be injured by the misapplication of the forceps before the sufficient natural dilatation of the passage, or by the misdirected force or undue haste with which instrumental delivery may be effected by injudicious practitioners.

Another occasional source of cicatricial obstruction or obliteration of the vagina is the abuse of escharotics or instruments intended for the treatment of uterine disease. It may also possibly result from syphilitic disease, as well as from phagedænic ulceration or direct injuries to the vulvo-vaginal orifice.

In the first volume of the *Transactions of the Academy* I have referred to my experience of the treatment of cases of vaginal occlusion, and regret that space prevents my now dwelling further on this subject, as such cases appear to me of much interest, not only from their comparative infrequency, but still more from the possibility of this condition being an occasional cause of menstrual retention, and an obstacle to impregnation or parturition. Moreover, they would serve to illustrate the special risk attending the surgical treatment of cicatricial vaginal obstructions. The latter point is one which should never be lost sight of in such cases. It was demonstrated by a distinguished Irish obstetrician, the late Dr. Evory Kennedy, in *The Dublin Quarterly Journal* many years ago, that the treatment of vaginal occlusion is by no means as safe as it is facile. This observation has been corroborated by recent writers, and more especially MM. Bernutz and Goupil, who have shown conclusively the risk of dividing these obstructions or adhesions by any cutting instrument, and the comparative safety of digital separation—the mortality following the use of the knife as compared with the surgeon's finger in such cases, being almost as three to one.

Chronic Endo-cervicitis as a Cause of Sterility.—Lastly,

we must here refer to another and more frequent factor in the causation of obstructive sterility and dysmenorrhœa—viz., what was formerly termed chronic inflammation, and since more properly designated areolar hyperplasia, of the cervix uteri. A brief glance at the pathology of this condition will show its importance in relation to the study of sterility. Suffice it to say that the theory by which this disease was for many years ascribed to idiopathic inflammation, leading to ulceration of the cervix uteri, has been long since abandoned, except, perhaps, by its author, and that it is now as generally regarded as the result of passive congestion, or hyperæmia, commencing in the cervical mucous membrane, the ciliated epithelium of which is thus primarily tumefied and softened, whilst later on the whole tract of the endo-uterine mucous membrane becomes disintegrated and hypertrophied. After a little time this hyperplasia extends to the subjacent muscular structures of the uterus generally, and gives rise therein to those sero-plastic exudations and infiltrations by which the effected parts are at first mechanically distended and thickened. As the disease goes on these plastic exudations becoming organised eventuate in new connective tissue, or true congestive hypertrophy, or areolar hyperplasia of the uterus. At the same same time follicular degeneration of the hypertrophied cervical glands occurs, and in their subsequent proliferation in most instances may be found the explanation of the conditions formerly regarded as the result of ulceration of the cervix uteri. The structural differences between the endo-uterine and endo-cervical mucous membrane are also of direct interest in this connection, explaining to some extent the greater proneness of the latter to hyperæmia, and the greater probability of this condition in the former being more immediately communicated to the underlying parenchyma. For whilst the ciliate membrane lining the cavity of the uterus is directly superimposed on the muscular substance, without the intervention of any sub-mucous layer, and has numerous utricular muscular fibre, the endo-cervical mucous membrane, on the contrary, rests on a sub-mucous layer, and is arranged in numerous folds branching off on either side from the central ridge, and thus presenting the appearance known as the *arbor vitæ*. This membrane is lined with ciliated epithelium, and interposed between its folds are countless racemose glands or Nabothian follicles opening between the ridges of the arbor-vitæ, and under diseased conditions pouring out that viscid, white-of-egg-like secretion so generally found blocking the os uteri and cervical canal in gynecological examinations.

In such cases the functions of the uterus are invariably disturbed. The menses are abnormal; generally they are attended by severe pain; in some instances they are diminished, but more commonly, menorrhagia as well as dysmenorrhœa result from the local congestion and irritation; and in a large proportion of cases of this kind I have observed that the abnormal menstruation recurred every third week, and lasted for six and seven days, whilst in the interval the patient was further weakened by the leucorrhœal discharge already spoken of.

Sterility almost always accompanies this disease, and as long as it exists to any serious extent the patient must remain barren. This fact, which I regard as of great practical importance, is too generally ignored in practice. I have known instances in which patients were subjected to active surgical treatment to overcome a supposed mechanical obstacle to impregnation, and who nevertheless remained childless, no attention having been paid to the

existence of chronic uterine congestion, on the subsequent cure of which pregnancy has followed.

General Treatment of Utero-Ovarian Hyperæmia leading to Sterility.—It would be out of place here to enter fully on so wide a subject as the treatment of the various phases of uterine hyperæmia productive of sterility. This I have elsewhere discussed,¹ hence I need not now allude to the local measures necessary in such cases, and shall merely refer very briefly to some few points which I regard as essential in connection with the general treatment of infecundity traceable to that condition.

At the present time medical attention is far too exclusively given to local treatment in all instances of chronic utero-ovarian hyperæmia; and whilst, for my own part, I attach as much importance to this as any gynecologist should do, I am convinced by experience that the reason cases of chronic endometritis, salpingitis, oöphoritis, and their cognate conditions so often prove obstinate and protracted in their course is that the improved methods of local treatment thus exclusively generally relied on are not aided by appropriate constitutional remedies. I have long urged the importance of the constitutional relations of certain forms of chronic utero-ovarian diseases, and have shown their general association with constitutional causes, and more especially with the strumous diathesis. I now again venture to call attention to the paramount importance of combining effective constitutional remedies with whatever topical measures may be found necessary in such cases, firmly believing as I do that they who thus judiciously employ general as well as local treatment, will be much more likely to cure their patients than those who rely altogether on the latter. In the majority of instances the subsidence of intra-uterine hyperplasia causing barrenness will be materially expedited by the administration of a course of bichloride of mercury, in minute doses, given in tincture of bark and continued for some time after the disappearance of all apparent local uterine congestion. In sterile patients of strumous diathesis, endometritis, in addition to the topical medication referred to, demands general treatment similar to that required in other local manifestations of this cachexia, and especially the use of those special alteratives and tonics with which the resources of modern polypharmacy have so abundantly supplied us.

Change of Climate and Mineral Waters in Certain Cases of Sterility and Dysmenorrhœa.—In dealing with cases of barrenness dependent on utero-ovarian complaints connected with the constitutional causes just referred to, and more especially in those associated with the strumous diathesis, the curative influence of a judicious change of climate and the utility of the various chalybeate, sulphurous, iodated, and arsenical mineral or thermal waters—which may be selected in accordance with the special exigencies of each case—is unquestionable. The accuracy of the views I have long maintained on this subject is sufficiently attested by the freedom with which they have been appropriated, and that, moreover, without any acknowledgment, by some recent writers from the works² in which I have shown the advantages, collateral and direct, of a visit to a suitable foreign spa,

¹ On the Constitutional Character and Treatment of Chronic Diseases of Women, etc. By Thomas More Madden, M.D., 1886.

² On change of Climate in Treatment of Chronic Diseases. T. More Madden, M.D., Third Edition, 1874. The Spas of Germany, France, and Italy. By the same, Second Edition, 1884. The Health Resorts of Europe and Africa. By Dr. More Madden. London and New York, 1886.

whenever, feasible, as a supplement to the local treatment adopted in chronic uterine affections. These benefits are not only the actual remedial effect of whatever mineral spring may be chosen, but still more the moral and physical benefits of the change of climate, occupation, and mode of living involved in the journey to any distant watering-place.

Whenever uterine or ovarian dysmenorrhœa, dependent on local hyperæmia, are present there is no remedy of such universal applicability as the prolonged use of warm or tepid baths. Nature has given us a wide choice of such baths, suitable for almost every form of chronic inflammatory uterine, and ovarian disease in the natural thermal springs which are found in almost every country. The waters which are used for this purpose are generally so feebly mineralised as to lead many to suppose that their effects are due to their mere temperature. Be this as it may, however, the fact remains that tepid thermal waters exercise a remarkable sedative action on the nervous and vascular systems. Under their use the frequency of the pulse is diminished, pain insensibly disappears, and all nervous irritation is gradually allayed. Effects such as these point them out as especially suitable for cases of chronic uterine hyperæmia, leading to sterility in hysterical women. Under these circumstances the effects of prolonged immersion of the body for hours together in water at the temperature of from 87° to 96°, or 98°, is peculiarly sedative. The spas which are available in this way, and from which I have myself seen most advantage in cases of chronic uterine disease, are those of Bath; Pfeffers, in Switzerland; Schlangenbad, in Nassau; Wildbad, in Wurtemberg; and Claudfontaine, in Belgium. To be of use these tepid thermal baths must be employed for long periods at a time, though it would probably be difficult to persuade ladies of the present day to stay in their baths as long as was at one time commonly the case at Pfeffers, when, as an old author assures us, patients remained in the water for whole days together.—“*Multa dies noctesque thermis non egredientur; sed cibum simul et somnium in his capiunt.*”

In sterile women, moreover, the gouty and rheumatic diatheses often show themselves in chronic uterine complaints, rather than in any of those external forms of the same constitutional disorders more commonly observed in the opposite sex. This fact, too generally ignored, explains the efficacy of alkaline mineral waters, such as Vichy, in many of the chronic uterine diseases of barren women of gouty habit, and utility of iodated and arsenical mineral springs, such as Kreuznach, Wildeg, Royat, and Monte Dore, which I have severally found of signal use in shortening the course of congestive hypertrophy of the uterus in women of these constitutional proclivities. By thus availing ourselves of all the varied resources of constitutional as well as local treatment in our dealings with chronic disease of the uterus, in our treatment of sterility, we shall, as I have before observed, best consult the advantage of our patients, and reflect credit on that gynæcological art which it is our province to cultivate, and to raise from that narrow specialism to which some would degrade it, to its true place as an integral portion of the great science of medicine.

Conclusion.—Ovarian and tubal inflammation, manifested by soreness, tumefaction, and occasionally burning pain in the ovarian region, is one of the most frequent consequences and accompaniments of uterine hyperæmia. In these cases the disease extends from the uterus, along the fallopian tubes to the ovaries, and this to a great extent accounts for the fact I have just mentioned, that patients suffering

from endo-metritis or endo-cervicitis, are sterile for the time being.

Were it not that I have already possibly exceeded the prescribed limit of time here allowed to readers of papers, I should have wished to state my experience with regard to the treatment of cases of sterility and obstructive dysmenorrhœa due, as is so often the case, to uterine flexions and displacements, and more especially to retroflexion of the uterus; or to fallopian tubal or ovarian causes, such as öophoritis and salpingitis, to which latter importance should be assigned in this connection, as well as to those just referred to. I must, however, rest content, for the present—as I hope to be allowed to return to this important subject on some future occasion—with having, in the foregoing communication, described the methods of treatment which I have found most successful in a large proportion of the numerous cases of barrenness and painful menstruation which have come under my care in the gynæcological department of my hospital and in private practice during the last few years. Moreover, I have also pointed out more briefly the principles which I believe should guide our treatment in the other forms of the complaints alluded to. I trust that the Academy will pardon the unavoidable length of this communication, and by a fair and full discussion of the views I have now submitted, aid practitioners in the curative treatment of a class of cases second to none in their importance and frequency.

THE GENERAL PRACTICAL USES OF ELECTRICITY IN MEDICINE AND SURGERY,

By W. E. STEAVENSON, M.D. (CANTAB.), M.R.C.P.,

IN CHARGE OF THE ELECTRICAL DEPARTMENT (LATE CASUALTY PHYSICIAN TO), ST. BARTHOLOMEW'S HOSPITAL; PHYSICIAN TO THE GROSVENOR HOSPITAL FOR WOMEN AND CHILDREN.

(Continued from page 108.)

Electrical Application in some Affections of the Genito-Urinary Organs.—Electricity is particularly useful in the treatment of affections of the genito-urinary organs for more reasons than one. In the first place, the lowest nervous centres or points for the transference of impulses from the afferent to the efferent nerves, which preside over these parts, are situated in the lumbar enlargement of the spinal cord, and a current of electricity can be so localised as to include the whole of this lower nervous system in the circuit. And in the second place, these organs communicate externally by narrow mucous passages, which enable them to be directly reached from without, when necessary for curative purposes, but offer serious difficulties to the employment of many agents that can be effectively used in other parts of the body. It is to these passages and parts difficult of access that the electrolytic properties of electricity, and galvano-cautery are found so adaptable and useful.

Incontinence of Urine.—Incontinence may be produced by a variety of causes. In children it may be due to the irritation produced by a too long foreskin, or to the irritation caused by ascarides, or to a too acid condition of the urine, usually accompanied by an excessive amount of oxalates, or to the presence of a stone in the bladder. Any of these causes having been detected, their removal is often sufficient to cure the enuresis. But there are other cases which are solely of a nervous origin; the patient can hold his water during the day, but at night sleep is so deep that the inhibitory control of the higher nervous centres over the reflex

centres in the spinal cord is in abeyance. Immediately any appreciable amount of urine collects in the bladder, a knowledge of its presence is transmitted along the afferent nerves to the spinal cord, and a message is returned for the bladder to expel it. These are the cases which are most readily amenable to electrical treatment. A pad (fig. 1) connected with the negative pole of a constant current

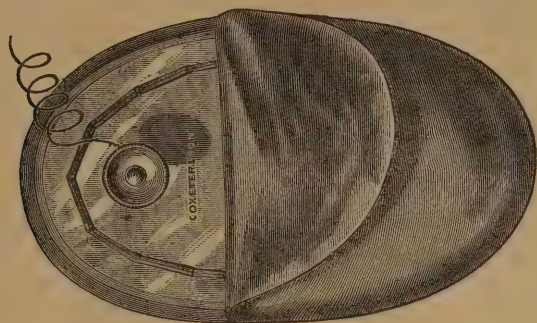

Fig. 1.

battery is placed over the lumbar enlargement of the cord, in the lower dorsal region, and a small button electrode (fig. 2) attached to the positive pole is placed on the perinæum. The whole nervous apparatus of the bladder is thus brought more thoroughly within the circuit than by any

Fig. 2.

other means, except that of placing an electrode into the urethra, a plan which can be avoided if cure is effected by the application of an electrode to the perinæum. The positive pole is applied to the perinæum, because it is less irritating, and the space is too limited to allow of the electrode being moved about more than an inch or two; we are, therefore, able to use a stronger current than if the poles were reversed. In some cases of troublesome frequency in micturition, occurring in adults suffering from locomotor ataxy, it is found that the negative pole on the spine increases the irritable condition of the spinal cord, and aggravates the infirmity. In these cases it is, therefore, sometimes found to be imperative that the positive pole, which possesses a sedative property, should be applied to the spine, and the negative to the perinæum. Adopting this plan, good results have been obtained.

There are other conditions in the adult which produce frequency of micturition, or involuntary expulsion of urine, such as enlarged prostate, or a hard bronchitic cough in old people, which cannot be cured by electricity applied in the way I have mentioned, although an enlarged prostate can be dealt with by electrolysis or galvano-cautery; but *cystitis*, which also causes frequent micturition, can often be relieved. It can also be caused by an incautious use of electricity, as was mentioned in my last paper. To relieve cystitis the bladder should contain some urine, or if empty, should be filled with tepid water, and a vesical electrode (fig. 3) should be passed into the bladder, but not allowed anywhere to touch its walls. The fluid surrounding the end of the electrode diffuses the current over the whole mucous surface of the bladder, and most likely the electricity acts beneficially by altering the condition of the mucous membrane, so as to render it more healthy. It is difficult to define accurately in what cases the beneficial effects of the current are due to its electrolytic action, and

those in which its stimulating properties, or influence as a nerve tonic, are of the greatest value. In all instances, no doubt the electrolytic power is brought into play more or less.

In the treatment of cystitis only a weak current of about five milliamperes is used for six or eight minutes at each application. The applications should be daily for the first five or six days, and then on alternate days for the remainder of the fortnight. In some cases galvanism has to be continued for a much longer period. Incontinence of urine

Fig. 3.

and atony of the bladder are very common in females, either from injury during parturition, or from prolonged retention, sometimes caused by an acutely anteflexed, or gravid uterus. Incontinence also sometimes follows forcible dilatation of the urethra, when made for the removal of a stone, or for the purpose of exploring the interior of the bladder. No treatment is so effectual in these cases as that by electricity. When there is atony of the walls of the bladder from over-distention, or any other cause, the constant current may be used as before described, with one electrode on the perinæum; but when there is inability to hold the water from over-dilatation or weakness of the urethra and sphincter vesicæ, then it is best to hold the metal point of the vesical electrode (fig. 3) in the urethra, and to use the interrupted current for ten minutes daily, or every other day, as strong as the patient is able to bear it. With the finger just within the vagina, to insure the electrode being kept in its proper place, the contractions of the muscular layer, forming the sphincter, can easily be felt. Inability to hold the water has also often occurred in the male after the dilatation of a stricture near the neck of the bladder. These cases should be treated in the same way with the Faradic current. The subject of the treatment of stricture of the urethra by electrolysis will be dealt with in the next paper.

I have already in the St. Bartholomew's Hospital Reports¹ recorded, five cases of atony of the bladder, in which the patients had lost the power of expelling urine, thirty-eight cases of enuresis, and five cases of cystitis accompanied by incontinence or frequent micturition. Nearly all the patients were either cured or relieved. Of the cases that were cured, six or eight applications of electricity were usually sufficient. One patient in Martha Ward, under the care of Dr. Matthews Duncan, had lost complete control over her bladder, from prolonged retention caused by the pressure of a retroverted gravid uterus on the neck of the organ and the urethra. Her water had been drawn off daily for nearly seven weeks. She recovered perfectly after four applications of electricity. Another patient from the same ward, suffering from pyuria, had had her urethra forcibly dilated for the purpose of exploring the bladder, and was subsequently troubled by incontinence. The urethra had been so stretched that it

¹ St. Bartholomew's Hospital Reports, vols. xix. and xxii,

could not recover itself, and the water was continually dribbling away. She had been in this uncomfortable state for several months when she was sent to me, and improved rapidly under electrical treatment. One young man, aged nineteen, had wetted his bed from infancy, and had been discharged from the militia on account of his infirmity. One woman, sent to me by Dr. Godson, had incontinence of urine when in an erect position. This was due to a prolapse of the posterior wall of the bladder and the anterior wall of the vagina, which dragged upon the urethra and slightly opened it. The prolapse had been the result of previous difficult labours. The electricity seemed to restore tone to the muscular walls of the vagina and bladder, and she was discharged quite well. Several of the patients were unable to retain their urine when making the slightest extraordinary exertion, such as going up stairs, lifting weights, and even when laughing or crying. Some are similarly afflicted when riding on horseback. I do not remember any of these cases which have failed to be cured by electricity. One case of incontinence followed a severe injury to the lower part of the spine. This patient had greatly improved before he left the hospital.

For the following abstract of three cases of enuresis, recently treated at St. Bartholomew's, I am indebted to my senior assistant in the Electrical Department, Mr. P. A. Houghton:—

Case 1.—George S——, aged seven, was admitted as an out-patient in November, 1887. Has never held his water properly since birth. Has control over his bladder in the day time. Wets his bed every night. Has nothing to drink late at night. No worms. Galvanism—negative pole to perinæum, positive to lumbar spine—current strength three milliamperes. December 3rd.—Still wets his bed, but not so soon after going to rest. January 13th, 1888.—Has gone the last fourteen days without wetting his bed. In this case there was gradual improvement for about seven weeks, after which there was a slight relapse, but the boy was unable to continue his attendance at the hospital. Instead of wetting his bed every night, he had so far improved as to hold his water without accident for fourteen consecutive nights before he discontinued treatment.

Case 2.—Lucy H——, aged eight years, was admitted an out-patient in December, 1887. Had scarlatina nine months ago. Since then has not been able to hold her water properly either by day or by night. Passes water as a rule every half-hour during the day. Wets the bed every night. Does not pass more water in the twenty-four hours than natural. Urine found to be quite normal. Galvanised. Positive pole applied to vulva, negative to lumbar spine. The current of strength was one milliamperè, passed for five minutes. This treatment was applied twice a week. In three week's time she could hold her water for four hours at a time. In a fortnight more she frequently went five and six hours. Has not wetted the bed for three weeks.

Case 3.—Ellen H——, aged seventeen, admitted an out-patient January, 1888. Increased frequency of micturition for the last four months. Passes water about every two hours in the day time, and rather oftener at night. Cannot keep any situation on account of her infirmity. The urine is quite normal. Catamenia are regular and natural. Has been taking medicines without any effect. Faradism to the neck of the bladder. A strong current was used. Passed for ten minutes twice a week. This was continued for six weeks. She had then gone a fortnight without wetting the

bed, and during the daytime goes about three or four hours.

In the treatment of *gleet* electricity has been found very successful. It is used somewhat in the same way as medicated bougies. The metal part of a vesical electrode or electrical bougie, such as is used in the treatment of stricture, is held against the sore unhealed surface which keeps up the discharge, and which is frequently to be found on the bladder side of a stricture. The electrode is made negative, and is moved slowly backwards and forwards over the sore surface for about two or three minutes, with a current strength of five milliamperes. The electrode connected with the positive pole is placed on some indifferent part of the body, but by preference over the lumbar enlargement of the cord, as possibly the effect of the electricity upon the nervous supply of the urethra may be beneficial. In the treatment of *gleet* no doubt the electrolytic property of the current is the chief agent at work. The unhealthy ulcerated surface on which the *gleet* depends is decomposed or altered in such a way as to put it into a condition in which it will heal.

Impotence, or inability to perform the sexual act, is also often greatly improved by electricity. It is employed for this purpose much more frequently in America and France than in our own country, but I have seen great improvement take place by "central galvanisation" as described in the first paper of this series (p. 57), chiefly by applying the negative electrode to the lower part of the spinal cord.

I mentioned in my last paper the good results obtained at Guy's Hospital, in the treatment of *amenorrhœa* by statical electricity. I have had a case sent to me by a well-known London surgeon, now retired, who possessed a large and fashionable practice. The patient, aged twenty-six, was a fine, well-developed girl, with a good complexion and clear skin, but did not appear to be quite so intelligent as most young women should be at the same age. She had not menstruated properly for eleven years, and had, during the last ten years suffered from epileptiform attacks. During the first two years these attacks came on about every three months, then every month until the year before I saw her, when the fits occurred every week, and sometimes oftener. Nearly every recognised remedy for *amenorrhœa* had been tried without effect, she was therefore sent to me to see whether electricity, applied direct to the uterus, would improve her condition. The uterus was found to be ill-developed, the sound entering only about an inch and a quarter. A pad was placed on the abdomen, above the pubes, attached to one pole of a Faradic battery, and a uterine electrode attached to the other pole was placed against the os uteri. The current was used eight times during the first two months, for ten minutes at each application, about the time it was supposed that menstruation should appear, because it corresponded with the time that the monthly epileptic fits used to appear previous to the last year. At the end of the second month some slight show occurred, which was repeated at the end of the third month, only one epileptic fit having occurred during the three months. At the end of the fourth month a very fair menstrual discharge took place, and the patient has been almost well since that time, now very nearly a year. During this period the patient has been brought by her mother for treatment about three times, because, from symptoms which had occurred, they dreaded a return of the epileptic fits; but the patient has been free for months together from any sign of giddiness or unconsciousness, menstruating regularly,

and losing at each period a fair quantity. This is quoted as being an extreme case, and one in which electricity had a marked beneficial effect.

In a discussion which followed a paper read by Dr. Gibbons, before the Obstetrical Society of London, in February, of last year, on a case of unilateral galactorrhœa,¹ which, while resisting all treatment, the flow of milk ceased spontaneously on the occurrence of menstruation, it was advocated as a mode of treatment in these cases that the function of menstruation should be re-established, and Dr. Routh² suggested the introduction of a foreign body into the cavity of the uterus, such as a small piece of nitrate of silver, to effect that purpose.

In the *British Medical Journal*, of April 30th, 1887, p. 926, is also a paper by Dr. James Braithwaite, of Leeds, in which he advocated the mechanical treatment of amenorrhœa by the introduction of small foreign bodies into the cavity of the uterus. He used to employ "a piece of hempen ligature, doubled several times, knotted, and impregnated with pitch. This was easily passed up to the fundus, without any preliminary dilatation, and then left there." He has more recently used stems of different patterns. The introduction of a piece of nitrate of silver into the uterus seems to be a most barbarous mode of treatment, and the other mechanical methods employed for stimulating or exciting the uterus, do not seem so free from objection as the use of the interrupted current. It would seem that if menstruation is to be established by the introduction of a foreign body into the uterus, the temporary presence, for ten minutes a day for a few days of a uterine electrode, is the least objectionable of any of the methods proposed. By the literature on the subject published in America and France, it would seem that Faradisation of the uterus for amenorrhœa is a well-recognised and frequent mode of treatment, and that the results obtained are highly satisfactory.

THE ELECTRICAL RESISTANCE OF THE BODY IN GRAVES' DISEASE.³

BY CECIL E. SHAW, M.A., M.D.,

CLINICAL ASSISTANT AT THE THROAT HOSPITAL, GOLDEN SQUARE, W.

DR. NORRIS WOLFENDEN demonstrated by observations made upon a series of thirty cases of Graves' disease the diagnostic value of a certain phenomenon attending this malady, which had been remarked by Charcot and Vigoroux in 1886. This phenomenon is the marked alteration in the resistance offered by the body to the passage of an electric current.

Normally, this resistance is more, often much more, than two thousand ohms, while in Graves' disease it is found to fall as low as five hundred occasionally, and it seldom continues to be over a thousand ohms for more than two or three successive observations if taken at an early period in the course of the disease—that is, before active treatment is begun. The method used in making these observations is fully described in the above-mentioned paper by Dr. Wolfenden: it is so simple that any person having the few necessary instruments may supply the test to suspected cases of Graves' disease in two or three minutes. I have lately had, at Dr. Wolfenden's clinic at Golden-square, the opportunity of measuring the electrical resistance in nine cases of Graves' disease and five cases

of simple gôitre. Having made a series of forty-six observations in these fourteen cases, the results seem sufficiently encouraging to be worth publishing, more especially as they confirm the results arrived at by Dr. Wolfenden. In making these experiments, cells were used sufficient to give an electro-motive force of eight volts.

The electrodes used were of metal, covered with chamois leather, about two inches in diameter, and were moistened in a saline solution before being applied, one at the back of the neck, and the other at the top of the sternum. The use of these "standard" electrodes eliminates that fruitful source of error, the old fashioned sponge. I shall give first the cases of Graves' disease, with the E.R. (electrical resistance) at various dates.

1. F. L., æt. sixteen, E.R. was on 27th January, 780 ohms; 31st January, 1000 ohms; and so on for eight observations, ending on 21st February, 4500 ohms. 2. M. G., æt. twenty-one, E.R. on 3rd February, 500 ohms; 14th February, 570 ohms. 3. A. L., æt. thirty-two, E.R. on 3rd February, 750 ohms. 4. A. C., æt. twenty-two, E.R. on 31st January, 625 ohms. 5. J. C. (sister of the last), æt. fourteen, E.R. on 3rd February, 1150 ohms. 6. A. P., æt. twenty-three, E.R. on 31st January, 1900 ohms; 10th February, 800 ohms; 21st February, 2300 ohms. 7. F. L., æt. eighteen, E.R. on 10th February, 1000 ohms; 14th February, 1000 ohms. 8. J. C., æt. nineteen, E.R. on 27th January, 550 ohms; 31st January, 750 ohms; and so on for six observations, steadily rising under treatment, to 1360 ohms on 17th February. 9. A. N., æt. thirty-six, E.R. on 27th January, 700 ohms; 31st January, 750 ohms; 3rd February, 600 ohms; 7th February, 1000 ohms; ending on 21st February, 900 ohms. The remaining five cases are simple gôitre. 10. S. G., æt. forty-seven, E.R. on 27th January, 4500 ohms; 3rd February, 7500 ohms; 10th February, 8000 ohms. 11. A. M., æt. thirteen, E.R. on 3rd February, 3000 ohms; 10th February, 2700 ohms. 12. E. I., æt. twenty-three, E.R. on 17th February, 7500 ohms. 13. J. B., æt. fifteen, E.R. on 7th February, 2000 ohms. 14. A. H., æt. twenty, E.R. on 27th January, 3500 ohms; 31st January, 3000; 10th February, 1150 ohms; 14th February, 2000 ohms, and so on; seven observations ending on 21st February, 4800 ohms.

A comparison of these cases will show that in only one of the cases of Graves' disease was the minimum resistance noted above 1000 ohms, that is No. 5, where only one observation was made, and the E.R. was 1150 ohms; while in only one case of simple gôitre did the E.R. ever fall so low as 1150, that is No. 14, and in this case it was much higher before than after. Seven of the cases of Graves' disease showed at some time in their course, when under observation, an E.R. of 800 ohms or less; while four of the cases of simple gôitre never fell below 2000 ohms. Thus it is seen that there is a broad distinction between the electrical resistance in the two sets of cases, and Dr. Wolfenden's conclusion that the method forms a most valuable aid to diagnosis between simple gôitre and early or undeveloped forms of Graves' disease is confirmed by my observations. The vast importance of noting this distinction is enforced by the fact that of the nine cases of Graves' disease, only one (No. 2) was what would be called a "well marked case," that is, showing considerable exophthalmos, von Graefe's sign, etc., and all might have been unrecognised by a careless observer. As the symptoms were so little advanced in many of these cases, while the E.R. was remarkably diminished, it hardly admits of doubt that many cases of Graves' disease might be

¹ Obstetrical Society's Transactions, vol. xxix., p. 59.

² *Ibid.*, p. III.

³ A Paper published last year in the *Practitioner*.

diagnosed very early by this method when the usual distinctive triad of symptoms was as yet undeveloped.

The cause of this diminution in the E.R. remains to be discovered. Dr. Wolfenden has suggested that it may be due to "vaso-motor dilatation of the skin capillaries," so I made notes of the pulse-rate, and the surface temperature in most of these cases. The speed of the pulse seems to have no relation whatever to the E.R., but the surface temperature shows an apparent relation. In seven out of nineteen observations the thermometer registered 90° or more, and in six of these seven cases the E.R. was at or below 1000 ohms. In several other cases, however, where the E.R. was as low as this, the thermometer did not rise higher than 88° or 89°, but this of course may be due to its not being held properly in contact with the skin, which is very difficult to ensure, unless the patient is constantly watched. I used Mayer's "Self-holding Surface Thermometer," which, however, cannot be trusted to hold itself, but must be retained in position by one finger pressing lightly upon it. About ten minutes is needed to bring the mercury up to its full height. No definite conclusion can correctly be drawn from the temperature observations.

THE VALUE OF MERCURY IN OPHTHALMIC PRACTICE.¹

By A. EMRYS-JONES, M.D.,

SURGEON TO THE ROYAL EYE HOSPITAL, MANCHESTER; OPHTHALMIC SURGEON TO THE BOLTON INFIRMARY.

It will be my aim in this paper to lay before you the result of my own clinical observation during the past twelve years at the Eye Hospital, at the ophthalmic department of the Bolton Infirmary, and also in private practice. As it is to be a *resumé* of personal experience, I shall not burden you with references to the opinions of others, but shall content myself with the selection of typical examples of the various affections of the eye in which I have found mercury of decided value. I must explain that it is to the *constitutional* effects of mercury that I refer, and therefore I shall not enter into details as to the value of mercurial preparations, like the red oxide, the yellow oxide, calomel, etc., in the treatment of blepharitis, phlyctenular conjunctivitis, and keratitis; nor to the antiseptic value of highly diluted solutions of the perchloride.

The topical, rather than the chronological, order will be observed. The first case that I shall therefore refer to is a case of—

Primary Chancre of Eyelid.—Thomas A.—, æt. twenty-two, attended the Eye Hospital on the 4th March, 1882. For the past six weeks he has suffered from a hard chancre on his penis, and also from what he described as a little inflammation of the right lower eyelid, which gradually got harder and more swollen. On examination, I found a considerable area of the lower lid punched out with its edges very hard and brawny, injection of the conjunctival sac, and swelling of the præ-auricular gland on the same side. Under the influence of mercurial ointment and the application of black wash externally, the condition of the eyelid became quite normal. He was then advised to continue under medical observation. This brief history well represents the course of this, by no means, common affection. My colleague, Dr. Mules, has at present (Feb.,

1888) a very peculiar example under his care at the Eye Hospital, which he was good enough to draw my attention to. A boy of seven was brought by his mother for what she considered an inflammation in the right eyelid. On examination, it turned out to be a well-marked primary chancre, accompanied by great swelling of the præ-auricular and sub-maxillary glands. He was at once put under mercury (inunction) with the very best results. It was impossible in this case to obtain any history as to how the disease had been contracted, but the necessity of accurate diagnosis will be apparent to all of you.

The next group of cases I shall refer to, is paralytic affection of the third nerve—

Paralysis of Third Nerve.—Ptosis.—Sarah M.—, æt. thirty-three, attended at the Eye Hospital, November 17th, 1883. There was history of syphilis communicated by her husband two years ago, and of continued ill-health, and, lately, great giddiness. At this date, well-marked ptosis in right eyelid, pupil sluggish to light, active to accommodation, movements of muscles inwards, upwards, and downwards much diminished. Ordered mercury in five-grain pills taken up to slight salivation.—December 21st, ptosis completely disappeared, and all the ocular movements normal. She afterwards took iodide of potassium, and has had no relapse.

Ptosis and Paralysis of Third Nerve.—Mary Yates, æt. three years, admitted to the Bolton Infirmary, December 22nd, 1885. Her mother said that seven weeks ago she noticed almost complete drooping of the *left* eyelid, and about a week later of the *right* eyelid. She could give no history of the cause, but said it was possible the child had been exposed to draughts. At that date we noticed there was ptosis of both eyelids. In the *left eye*, complete paralysis of internal and inferior recti muscles. In the *right eye*, paralysis of superior and inferior recti muscles. No dilatation of the pupils; vision normal in both eyes; urine, sp. gr., 1020, no phosphates, no albumen. The child was admitted as an in-patient, and mercurial inunction was resorted to.—On the 30th, she was fully under the influence of mercury, and inunction stopped. Already the ptosis was less marked, and the action of the paralysed recti restored slightly. Half-grain doses of iodide of potassium thrice daily ordered.—January 20th, no ptosis; ocular movements perfect; and the eyes, in every respect, normal. The rapidity with which the child was affected by mercury is explained by the fact that she had been taking it in small doses before she was put under my care. I could detect no symptoms indicating a central lesion in this case, but it affords an instructive example of the value of the drug in such cases.

I have not met with typical examples of *gummatous growths in the orbit*, causing exophthalmos, etc., but a recent case under the care of Dr. Mules, which he has kindly permitted me to mention, will answer my purpose very well. The patient was a middle-aged woman, with a large solid growth, pushing the eye downwards and slightly outwards, and with very obscure history. Dr. Mules, one day, was almost tempted to make an exploratory incision, but before doing so he determined to try mercury, and after giving it for some weeks without producing very marked effects on the growth, iodide of potassium was substituted with the happy result that the growth entirely disappeared, and the eye resumed its normal position.

Before entering upon affections of the cornea, I would like to say that in the *interstitial form of keratitis*, due to inherited syphilis, I have found mercury of comparatively

¹ Paper read before the Clinical Society of Manchester, February 21st, 1888.

little use. I have often tried it, but have been almost invariably disappointed with the results. Mr. Jonathan Hutchison speaks well of the use of hydrarg. c. creta. in one grain doses thrice daily.

In Descemetitis—i.e., deposits of flakes on Descemet's membrane—i.e., the posterior corneal layer often associated with, and due to deeper-seated diseases of the iris, and choroid; mercury is of signal service, and, in some cases, it acts with extreme rapidity as in the following case:—George W—, æt. sixteen, first seen September 11th, 1886. He said his vision was quite good up to a fortnight ago. At date, vision in right eye $\frac{1}{8}$; well-marked coarse deposits on Descemet's membrane; choroiditis; and recent exudation above the optic disc. Ordered pil. hydrarg., gr. 3, thrice daily.—On the 25th, the deposits on the cornea and the retinal effusion had entirely disappeared, and the vision quite normal.

Iritis with Descemetitis.—Chas. W—, æt. seventeen, Huddersfield, admitted an in-patient to the Eye Hospital on December 7th, 1887. Right eye inflamed two years ago; got better, but was inflamed again one year ago; no history of gout or syphilis. Left eye normal in appearance, and vision. Right eye small patch of punctated keratitis; pupil irregular; numerous synechiæ posterior. Details of fundus cannot be satisfactorily examined; vision, $\frac{1}{8}$. Ordered pil. hydrarg. and mist. pot. iod.; atropine.—December 17th. Fewer adhesions; vision, R.— $\frac{5}{8}$. On February 3rd, 1888, I saw him again: vision in both eyes normal, and Descemet's membrane quite clear.

I shall enumerate several cases of *affections of the iris*, as we have in mercury a valuable aid in their treatment. In all cases of iritis the surgeon should endeavour by the frequent instillation of atropine (four grains to the ounce of water) to dilate the pupil fully. If the attempt be successful in the course of a few days, atropine alone will complete the cure; but if not, it will be necessary to administer mercury in some form or another. The plan I personally prefer, where it can be adopted (and by this I mean where the patient can be kept in a uniform temperature, and under careful observation) is by *unction*. Either the ordinary mercurial ointment, or the oleates, may be spread on a piece of flannel, and bandaged on to the arm. Rubbing is sometimes recommended, but it may produce irritation, and considerably impair the absorbing power of the skin. This plan of administration is much less liable to disagree or produce unpleasant sensations and digestive derangements than by giving it internally. I know of no proof of the direct action of a drug similar to that of the action of mercury on iritic adhesions, if not of too long standing. Atropine by its aid seems to break down one tag after another, until the pupil is dilated equally all round. As soon as the adhesions are completely broken down, or even before, if the gums are tender, the mercury should be stopped, and iodide of potassium substituted, and if necessary, mercury may be afterwards resorted to.

Syphilitic Iritis.—Sarah McL., æt. 35, admitted as an in-patient, Bolton Infirmary, October 19th, 1886. She said her eyes were quite strong up to ten days ago, when they became very dim and foggy. She had had a syphilitic rash for four months, and sore throat. At present her vision is very bad, and she can scarcely see her way about. On examination well-marked iritis in both eyes; the iris is muddy, and its structure masked by the abundant exudation; the pupillary space seems filled with uveal pigment; adhesions all round, and atropine has but little effect in

dilating the pupil. Immediately after her admission she was ordered perchloride of mercury in large doses, as she had also taken mercury before her admission.

In less than a week there was slight salivation, and evidence of one iritic adhesion after another giving way. December 16th—i.e., less than a month after her admission—every trace of iritic adhesion had disappeared, iris seemed natural in colour, no vitreous opacities. Vision R. and L., with correcting glasses, normal. She was sent home and ordered iodide of potassium.

This case is a typical example of the value of mercury in this frequent affection; but it is the experience of all ophthalmic surgeons that cases of syphilitic iritis that are not diagnosed early, and put under anti-specific treatment, go on to complete annular synechiæ, develop glaucomatous symptoms, and result very badly.

Janet F., æt. twenty-five, admitted as an in-patient at the Eye Hospital, December 13th, 1882. She gave the following history: She was confined on the 2nd of August, 1882, and for six weeks prior to that date, she had been out of sorts, but had no spots on the body—no sore throat. Three days after her confinement spots came out all over her body; she had severe sore throat, and noticed an alarming falling off of her hair. The baby was quite clear when born, but when about two months old she noticed some purple spots, especially on the buttocks. Last September she began to be troubled with her eyes, suffering from severe pain and dimness, and inability to bear the light. At that date there was deep conjunctival injection in both eyes. Iris muddy; extensive synechiæ, which did not give way in the least after the frequent instillation of atropine for three days. Fundus oculi cannot be detected on account of the hazy media in both eyes. Vision in R. and L. $\frac{6}{8}$ scarcely. She was ordered mercurial inunction on the day of her admission, and in a week slight salivation was noticed, and the following notes made: Right eye—pupil fairly dilated all round; Left eye—extensive adhesions. Patient looks much better. Mercury stopped and iodide ordered.—December 27th. Vision: R. eye, $\frac{6}{8}$, i.e. normal, iris clear, pupil wide; L. eye, $\frac{1}{2}$, iris clear, still a few adhesions. Patient looks quite well, and expresses herself as feeling quite a “new being.” Spots on body completely disappeared.

Recurrent Iritis—Condyloma—Recurrent.—Mrs. P., æt. thirty-one, consulted me on the 29th of December, 1883. She said the left eye had been bad since September, and that she thought she had caught the ophthalmia from the children at her school. The sight was fairly good up to the first week in December. When I saw her—Vision: L. eye, $\frac{6}{8}$. I could detect a large condyloma below encroaching on the pupil. Vitreous hazy; iris muddy. Ordered gtt. atrop. and ung. hyd.—January 14th. Condyloma has disappeared, pupil dilated, no pain; vision normal. Ordered mist. pot. iod. She came back again on the 2nd March, 1884, and said she had a cold on her journey home. Vision: left eye counts two fingers; pupils fairly dilated, but media very hazy. Ordered hydrarg. perchlor. and pil. hyd. iod. vir.—March 14th. Abundant adhesions (synechiæ posterior); cannot see retina; vision 19 Jäger vix. Mercury pushed to salivation, which occurred on March 28th, and at this date I ordered syr. ferri iod. and ext. sarsæ liq.—August 23rd. A few synechiæ; O. nerve healthy; no pain; no active inflammation. Vision normal, $\frac{1}{6}$, and has remained so up to now.

In this case I never succeeded in getting an admission of syphilis, but I had not the slightest doubt of it, and I

consequently pursued the treatment on the right lines, and obtained satisfactory results. This case points to the necessity of *prolonged* treatment and watching, and that it is necessary to be guarded when we are asked if there be any danger of recurrence.

Iritis—Retinitis.—Ellen W., æt. twenty-six, of Padiham, first consulted me on the 2nd of December, 1882. Two years previously she had severe inflammation in both eyes, and was attended to for some time by a local doctor. Was an in-patient at the Eye Hospital for twelve months, and had undergone a double ireductomy. She has had no active inflammation since, up to date (December, 1882); but her sight has been getting gradually worse, and she has been told that nothing more could be done. On examination I found evidence of retinitis in both eyes, and although I could get no admission of specific inoculation (Vision: R. 16 J.; L. 20 J.) I ordered her large doses of Donovan's mixture, and the vision in less than a month improved to R. $\frac{6}{60}$; L. 19, and her health was improved. —March 31st, 1883. Vision same in L.; R. $\frac{6}{60}$ c. + 4d. = 1 J. Vision kept moderately good up to March, 1887, when she came again with both eyes very bad. Vision: R. perception; L. 20. I ordered her ung. hydrarg. and used it to salivation. Vision improved to R. 20 J., L. 16 J.

I have seen her again just lately (December, 1887) and in spite of all treatment her vision has gradually deteriorated, and now she can scarcely see her way about, and the tension is below normal in both eyes.

This case presents several features of interest. At first, and for some time, it shows a decided improvement under mercurial treatment, but it further illustrates the necessity of watching our cases for a long time before giving a too-decided prognosis.

Retinitis.—Emma S. æt. 41, Oldham, first attended at the Eye Hospital on the 30th of September, 1881. She said she had been in good health up to two years ago, when she began to suffer from very severe headache, which had been growing worse lately. No history of syphilis, no sore throat, no spots. Vision: R. 1 J. $\frac{6}{12}$; L. 20 J.

Ophthalmoscopically—the retina in both eyes was very hazy; margins of optic nerves fairly well-defined. Ordered ung. hydrarg. externally, and mist. quin. et ferri internally. On the 8th November, 1881, the retinæ were clear, headache entirely disappeared, and vision quite normal.

I have seen many cases of simple retinitis recover very rapidly under the influence of mercury carefully administered.

Neuro-Retinitis, Syphilitic.—Ann P., æt. thirty-seven, first attended at the Eye Hospital, November 30th, 1881. She had been complaining of bad sight for the past seven months, and was much troubled with black spots and floating bodies since her confinement, in May. She had suffered from sore throat, and at the time of her visit she had a copious coppery eruption over her body, and her child had shown syphilitic symptoms.

Vision R. and L. $\frac{6}{60}$. Ophthalmoscopically it was found to be a well-marked case of neuro-retinitis; margins of optic nerves ill defined, and a general haze all over the retina. There was no iritis. Ordered ung. hydrarg. externally, and iodide of potassium internally.—December 7th, 1881. Vision: R. and L. $\frac{6}{12}$, and on June 11th, 1882, when I last saw her, her vision was R. and L. $\frac{6}{60}$, optic nerves and retinæ clear.

Atrophy of the Optic Nerves following Optic Neuritis.—James D.—, æt. nineteen, admitted as an out-patient

in the Royal Eye Hospital, February 3rd, 1883. He said that he was quite well up to a few days ago, and could see well with both eyes. He felt pricking pains in both eyes, and last Tuesday—i.e., four days ago, he noticed he could not see at all with the left eye; no vomiting; no headache. He complains of stiffness and numbness of hands and feet. When walking he separates his legs, and plants them with difficulty; the staggering is a good deal worse when his eyes are closed. Tendo reflex exaggerated.

V. Right; 19 J. vix. } Well marked optic neuritis in Left; fingers at 4 inches } both eyes; veins engorged, arteries small; optic nerves woolly, with ill-defined margins. Ordered potass. iod.—February 14th, 1883, he was admitted an in-patient. Pupils active and normal in both eyes. Optic neuritis not so marked; veins engorged: discs irregular in their outline. Vision: R. 14, L. 16 J.—February 21st. R. $\frac{12}{60}$, L. 14 J. Tendo reflex highly exaggerated; also ankle clonus.—February 28th. Vision: R. $\frac{1}{18}$, L. $\frac{14}{60}$.—March 7th: left hospital; both optic nerves look pale; no neuritis. I lost sight of this case entirely until the 17th of February, 1887, when he was again admitted as an in-patient at the Eye Hospital, when he reported that since we saw him before, the sight in both eyes had varied greatly. At this date both optic nerves were pale and atrophic; slight choroiditis at their outer margins; vessels good size. Fields for white contracted; fields for red much contracted; especially in the right eye. Vision: R. + 4d = $\frac{6}{24}$, L. J. 20 vix. Ordered perchloride of mercury and iodide of potassium.—March 19th, 1887: R. $\frac{6}{60}$, L. $\frac{6}{60}$.—February 10th, 1888. I sent for him, and made a complete examination. Vision: R. $\frac{6}{12}$, L. $\frac{6}{18}$; optic nerves quite pale and white. He has had no attacks for a year. Fields still contracted.

Atrophy of Optic Nerves. Ptosis and Paralysis 3rd Nerve.

—Lewis G.—, æt. forty-five, admitted an in-patient to the Eye Hospital on October 7th, 1885. History: The sight of both eyes has been failing markedly for three years, and getting gradually worse. No admission of syphilis. Palms of hands and fingers show some fissures, and appear moist and scaly. Tendo reflex good. He has been a heavy smoker. Vision: Right eye, 20 J. vix. Optic nerves pale and atrophic, especially at outer part. Left eye: Entire absence of movements inwards; also of direct movements upwards and downwards. On attempting to look upwards the eye is moved slightly up, but it also rotates inwards; and in attempting to look down the eye is slightly rotated outwards. Vision, left eye: shadows. Optic nerve paler than the right. Ordered ung. hydrarg. to be pushed.—October 21st, 1885. Signs of salivation. Vision: R. 6 n4, L. 19. At this time the fields of vision were carefully taken by Mr. Roberts, the house surgeon. Right: Field for white considerably contracted all round; field for red much contracted; central scotoma of considerable size. Left: Field for white much more contracted than right; field for red slightly larger; central scotoma of equal size.—November 7th, 1885. Vision: R. $\frac{6}{60}$, L. $\frac{6}{60}$.—December 20th, 1885. Stopped hydrarg. Vision: R. $\frac{10}{12}$ 6 J., L. $\frac{6}{60}$. Field again taken. No central scotoma in right, and in left only a very small central scotoma for red, but not for white. Green called white in both eyes. Not much difference in the appearance of optic nerves. This patient wrote lately to say that his vision had further improved since I last saw him, and that he had been able to follow his employment, although at one time before I saw him he had given up all hopes of ever being able to do so.

Atrophy of Optic Nerves.—Thomas D—, æt. twenty-two, admitted as an in-patient, Eye Hospital, July 11th, 1882. History: He came as an out-patient on May 13th, 1882, when he said his vision was quite good up to two months ago. A fortnight ago he noticed that the left eye was the worst. He has smoked one ounce of thick twist a week, and drinks beer, but not to excess. History of syphilis (hard chancre) eight years ago, but has felt no evil results since. His vision then was, R. $1\frac{6}{8}$ —i.e., normal, L. $4\frac{6}{8}$.—June 24th. R. $\frac{6}{8}$, normal; L. 19 J. Ophthalmoscopically: Left optic nerve very pale. Ordered mist. quin. et. strychn. On admission as in-patient his vision was—R. shadows; pupil active; signs of incipient atrophy of nerve. L. 19 Jager; pupil active; optic nerve pale and atrophic. Ordered mercurial inunction. In a week salivation. Mercury stopped and iodide ordered.—August 2nd. Vision greatly improved: R. and L. 4 J., $\frac{6}{8}$.—August 11th. House surgeon notes discs pale, vessels small. Vision: R. $1\frac{6}{8}$, L. $1\frac{6}{4}$.

Optic Neuritis with Hæmorrhages.—John M—, æt. forty-nine, first attended the Eye Hospital on January 19th, 1884, when he gave the following history: His sight was good up to six months ago; since then gradually failing; no pain in head; no vomiting; no loss of memory; no staggering gait. Two children living and healthy. Pupils fairly active. Ophthalmoscopically: some vitreous haziness in both eyes. Right eye: Blurring of disc and surrounding retina; apparently not much swelling of disc, but almost complete obscuration of edges; one hæmorrhagic spot on the inner side. Left eye same, but no hæmorrhages. Vision: R. $\frac{3}{8}$ vix, L. $\frac{3}{8}$. He was ordered ung. hydrarg. and iodide of potassium by Dr. Mules, under whose care he was at that time; and by February 27th, 1884, his vision had improved: R. $\frac{6}{8}$, L. $\frac{6}{8}$ vix. On March 6th, 1884, there was a large membranous opacity in the right vitreous. Left vitreous clear; still swelling of disc and opacity of surrounding retina. On December 13th, 1884, he came under my care, when I noticed that both discs and surrounding retinæ were hazy. No hæmorrhages. Vision: 19 J. both eyes. Ordered Donovan's mixture.—February 18th, 16 J. R. and L. At this date ordered mist. hydrarg. perchlor. Vision continued same.—March 10th, 1885. Gave mist. Donovan. Vision at this date R. +6=9; appearance of optic nerves healthier.—January 10th, 1885. Vision: R. 18 $\frac{6}{8}$, L. 18. Still films in vitreous. The result in this case is by no means brilliant; but I believe the use of mercury in various forms prevented the nerves becoming completely atrophied.

Choroiditis Disseminata.—Owen J—, æt. forty-nine, of Beaumaris, consulted me on the 4th of December, 1881. He said that he had had "slow fever" a year previously, and had been in bad health, and this led me to suspect its syphilitic origin; he had seen things double, and could see better at twilight, and could not retain retinal impressions for any length of time. Field of vision much contracted all round in both eyes. He has not been a heavy smoker. Ophthalmoscopic examination revealed:—Right eye, a large atrophic patch in region of yellow spot; Vision: 16 Jager scarcely. Left eye, extensive choroiditis, with numerous exudations, and a few small hæmorrhages, and patches of pigment. Although I could not get any history of syphilis, I inferred it, and ordered ten-grain doses of potass. iodid.—November 23rd, 1881. Saw again; vision in left eye slightly improved, L. $12\frac{6}{8}$. I determined then to try mercurial ointment. He continued with this until February, 1882, where slight salivation

occurred, and his vision then was, R. 16; L. $10\frac{6}{8}$, c.+4d.=6 J. As he was now in a low general condition, I ordered him maltine, and cod liver oil, and strychnine, and by March he had gained six lbs. in weight, and had entirely got rid of his feelings of depression and nervousness. For three months longer, tonics and mercurials were prescribed alternately, and when I saw him last on the 11th of October, 1882, he had gained ten lbs. more in weight, i.e., sixteen lb. since I first saw him a year previously. The vision in the worst eye, the Right, had improved to 14 J., $\frac{6}{8}$; Left eye, $\frac{1}{8}$, c.+4d.=1 Jager easily. This gentleman had been under skilled treatment for more than a year before I saw him, and his vision went gradually worse. I attribute the success entirely to the detection of the cause, which was undoubtedly somewhat obscure.

Central Choroido-Retinitis-Macular.—Amy McC—, æt. thirteen, Manchester, first seen as an out-patient, Royal Eye Hospital, June 26th, 1886, then her paper was marked amblyopia, with correcting glasses= $\frac{6}{8}$, after atropine +2d.= $\frac{6}{8}$. R. and L. sight bad for six months.—January 30th, 1886. Peripheral fields, with fingers contracted R. and L. (tested with fingers), with +1d. sph.= $\frac{6}{8}$; no retinal change detected.—July 3rd, 1886. Again seen, but no retinal change noted. She went to London, and was seen by Mr. Couper, at Moorfields, on the 27th of July, 1886, when her vision was marked R. and L. 20—sees hand. Glasses do not improve. The following notes I copy from the paper sent with her from London: Left eye; greyish change and ædematous halo round the macula; atrophy of pigment at macula; fine granular change very marked at fovea. Right eye, ditto. She was ordered syr. ferri iod. and pulv. hyd. c. cret., gr. $\frac{1}{2}$, twice a day. August 24th, 1886. Vision: R. and L. $\frac{6}{8}$; ordered gr. i. of the hyd. c. cret.—September 7th, 1886. R. and L. $\frac{6}{8}$, c.+1d.= $\frac{6}{4}$ nearly. Left macula change less easily seen. Right, also; but halo still visible. She then returned to Manchester, and I saw her on the 15th of September, 1886, when the condition was as described by Mr. Couper. Ordered her to continue with the hyd. c. cret.—December 28th, 1886, c.+1d.= $\frac{6}{8}$ R. and L.—May 24th, 1887. Left off treatment. Vision quite normal in both eyes; no ophthalmoscopic changes can be detected.

Central Choroiditis with Retinitis.—Arthur C—, æt. twenty, Romiley, admitted as an in-patient, Royal Eye Hospital, on the 23rd of October, 1887. He is by occupation a clerk. He says he does not remember seeing very well with the Right eye, and the Left has been failing him for the past ten weeks. He has no headaches. Health not strong, but he has not complained of any special disease. No history of syphilis. Ophthalmoscopic examination: Right eye, a small crater-shaped central choroiditis can be detected. Vision: $\frac{6}{8}$. Left eye: optic disc blurred; margin indistinct; small patch of choroiditis, with a few retinal hæmorrhages. Vision: $\frac{6}{8}$. Ordered ung. hydrarg. November 12th, 1887. Vision same; less choroido-retinitis in left eye.—November 19th. Vision improved in both eyes: R. $\frac{6}{8}$, L. $\frac{6}{8}$.—November 26th. Vision relapsed to R. $\frac{6}{8}$, L. $1\frac{6}{8}$. Ordered perchloride of mercury internally. Saw again February 3rd: R. $\frac{6}{8}$, L. $\frac{6}{8}$. Fundus clearer.—February 10th, 1888. Vision R. and L. normal. The atrophic patches can still be discerned on both retinal, and he continues under treatment and observation.

I must express my indebtedness to the house surgeons at the Manchester Eye Hospital and the Bolton Infirmary for their careful record of the cases under my care, and I hope that the interesting group of cases now presented will be of service as commentaries to my professional brethren.

DYSMENORRHOEA.¹

BY AMAND ROUTH, M.D., B.S. LOND., M.R.C.P. LOND.,

ASSISTANT OBSTETRIC PHYSICIAN, CHARING-CROSS HOSPITAL; PHYSICIAN TO THE SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.

DYSMENORRHOEA is the function of menstruation performed with difficulty and pain, and is more important than most disordered functions, in that it may carry with it a train of gastric, cerebral, and nervous phenomena, as distressing as the pain itself. It is a *symptom*, not a disease. To remove the symptom, we must find and remove its cause. The *pain* is common to all cases; its site, character, time of onset, duration, with the reflex phenomena and the previous history, may all vary according to the *causation* of that pain.

In the consideration of this subject so much depends upon the circulation of the uterus, that I must here devote to it a small space. The uterus is supplied from the abdominal aorta and internal iliac by means of the ovarian and uterine arteries, which run towards the fundus and cervix, between the layers of the broad ligament on either side of the uterus. Just before reaching that organ, they run downwards and upwards, *outside* and along the whole length of its long axis to anastomose. From these two main resulting vessels, a series of double branches jut out, penetrating through the muscular layer of the uterus into the sub-mucous layer, there forming complete circles, from which twigs are given off into the deep and decidual layers of the mucous membrane. This rather peculiar vascular supply explains the fact that acute, often congenital, antelexions may be unsymptomatic and free from congestion; for it is clear that so long as the main arteries and veins, which we have seen to be external to the uterine tissue, are not interfered with, a ligature even, applied round the uterus, would not arrest its circulation either above or below. It explains also the fact that backward displacements of the uterus, *with descent*, produce more or less severe congestion; for here the fundus uteri, together with the broad ligaments containing the vessels, gets grasped by the sacro-uterine ligaments, which then assume the function of the neck of the sac in an intestinal hernia, necessarily causing much interference with the arterial, and especially with the venous supply.

Menstruation.—In whatever way menstruation is influenced by ovulation, it is preceded by a determination of blood to the sexual organs, which causes their temporary hypertrophy, influencing, moreover, such distant organs as the mammae, and even the thyroid glands. The larger these organs are during the inter-menstrual periods, the greater will be their relative hypertrophy, as one may see in fibroid tumours of the uterus, in prolapsed ovaries, in adenomatous mammae, and in goitrous thyroids. During the preliminary engorgement stage, the mucous membrane becomes swollen and thrown into folds, and the mucous glands secrete abundantly, producing more or less leucorrhœa. Hæmorrhage, from rupture of the small capillaries in or beneath the thin upper or deciduous layer of mucous membrane, soon follows.

Causes of Dysmenorrhœa.—These are, roughly, local and constitutional, though both sets of causes may be present. Successful treatment necessarily depends upon tracing

back the symptom—the dysmenorrhœa—to its origin. The local causes may be divided into the following groups:

- | | | | |
|-----------------|-----------------------------|-------------------------|-----------------------|
| LOCAL. | { | 1. Spasmodic (? local). | |
| | | 2. Obstructive | { Stenosis (organic). |
| | | | { Displacements. |
| | | | { Fibroids. |
| 3. Inflammatory | { Altered uterine contents. | | |
| | { Uterine. | | |
| | { Tubal. | | |
| 4. Congestive | { Ovarian. | | |
| | { Peri-uterine. | | |
| | { Primary. | | |
| | | { Secondary. | |

Our first heading is the so-called *spasmodic dysmenorrhœa*, which may be quite independent of either local or constitutional disease, and is then probably of the nature of a neurosis. In other cases it may be accompanied by, and perhaps caused by mechanical obstruction, or inflammation, or the irritating presence of a fibroid, and thus seriously aggravates the dysmenorrhœa due to those conditions, just as spasm of the bronchial tubes aggravates bronchitis. Some call this form “neuralgia”; others do not believe that these painful contractions—“uterine colic,” or “uterine cramp”—can occur apart from obstruction, and they would accordingly combine this with the “obstructive” form of dysmenorrhœa.

Spasmodic dysmenorrhœa is one of the commonest—often the most painful, and when uncomplicated by organic changes, and of recent date, is fortunately one of the easiest forms to cure, though some long-standing cases obstinately resist all treatment. It is due to painful contraction of the hollow uterine muscle, and may accordingly be either clonic, “come and go,” producing intermittent pains, or tonic, producing incessant pains. These painful contractions are not due to the uterine muscle contracting to expel its contents, but are purely spasmodic, and in a really typical case occur when the uterus is empty, and are then more severe than even the obstructive pains of membranous dysmenorrhœa. They resemble, in fact, the severer form of “after-pains,” of which there are two main types, so well studied by Matthews Duncan. The least severe and least prolonged, always clonic “after-pains,” are those where a piece of retained placenta or clot is the exciting cause, the pain ceasing when this is expelled. The most severe and most prolonged, usually tonic “after-pains,” occur when the recently-emptied uterus goes into the most violent contractions, without any such object in view. We give ergot to aid the uterus to expel its contents in the first form, and sedative in the second form to allay the spasms. These spasms or cramps of the uterine muscle are the main causes of the partial or entire detachment of the decidua menstrualis in membranous dysmenorrhœa, and by curing the former we usually cure the latter. Spasmodic dysmenorrhœa comes on usually at puberty, and may in time, as the constitutional tone improves, wear itself out, though it may become more severe, especially if an unfruitful marriage ensue, leading then to organic changes, with other super-added forms of dysmenorrhœa.

The pain always precedes the menstrual flow, sometimes by ten days or a week, being usually most severe just *before* the flow begins, diminishing as it appears, and ceasing at the end of the first or second day. This proves that the dysmenorrhœa is not due to obstruction, for then the more there was to pass, the worse would be the pain, whereas women constantly declare that they have most pain when they have the least flow (unlike obstructive dysmenorrhœa).

¹ A Post Graduate Lecture, delivered at Charing-Cross Hospital, on January 6th, 1888.

Thus it happens that when spasmodic and obstructive dysmenorrhœa co-exist in the same patient, we may have the pains, due to the former, ceasing as the flow appears, followed by a few hours, or a day or two, of freedom from pain, to be followed again by the "come and go" pains, due to obstruction to the exit of blood or clots. The pain sometimes simulates peritonitis, but this is easily negated by the apyrexia. During the progress of the pain it is easy to prove the absence of obstruction; for at the very acme of the pain, a few hours before the flow appears, a bougie, No. 7, 8, or 9, will pass easily along the whole length of the uterine canal. Emmet has shown that of married women who originally had spasmodic dysmenorrhœa, 71.6 per cent. are sterile—a very important fact, showing the need for treatment, when we consider that the worst cases do not marry.

Obstructive Dysmenorrhœa.—Barnes say: "For menstruation to occur easily and healthily, the genital canal, from its commencement at the fimbriated extremities of the fallopian tubes to the vulva, must be pervious." Any such obstruction, though constantly present, may only produce discomfort as the periodic metrostaxis comes round. Obstructive dysmenorrhœa in its typical form comes on *immediately* before or simultaneously with the first external manifestation of the metrostaxis, or it may be delayed till sufficient blood is poured out to make the obstruction a real one. I cannot here allude to the necessity or avoidance of local examination, but it is obvious that in obstructive dysmenorrhœa a correct diagnosis can only be thereby obtained. Where, however, we have reason to believe the patient is a virgin, we may examine first per rectum, previously intimating our intention to the patient; and though such an examination is very unpleasant to the patient—and, indeed, to the examining physician—one's object is appreciated. We can thus make out the position, mobility, and size of the womb, and often the condition of the ovaries and broad ligaments. If necessary, a vaginal examination can then be made, and the state of the cervix and endometrium explored. If the hymen be unyielding, an anæsthetic may be required.

Displacements of the womb and ovaries may occasionally produce dysmenorrhœa, though their importance has been till lately too much dwelt upon. This is mainly due to the fact that when patients complaining of dysmenorrhœa are examined, it is found that in many cases the uterus is deviating from its normal anteverted position. To make my meaning clear as regards the true significance of ordinary flexions, I will suppose that a patient comes with a long train of subjective symptoms, inclusive of dysmenorrhœa, and that on examination we find a retroflexed womb. We assume this is the cause, and insert a well-fitting Hodge pessary, which did two things—viz., kept the uterus at rest, and kept it at a higher level; and we may have thought, erroneously again, that it was going to do a third thing—viz., to turn the retroflexion into a normal anteversion. After some time, if we are fortunate, our patient is cured of her subjective symptoms, and we remove the pessary, and examine again, and find the uterus with exactly the same flexion as regards its own component parts, but—and this is the secret—that the uterus is higher up in the pelvis, disengaged, in fact, from the sacro-uterine ligaments, and thus relieved of its congestion; and so long as this level is maintained, all will be well, but as soon as the womb sags down again, and becomes again congested, all the old troubles will recur. It will thus be seen that flexions *per se* rarely cause obstruction, but that

when accompanied by prolapse, congestion often ensues. Dysmenorrhœa, therefore, due to displacements would be better considered under congestive dysmenorrhœa.

There is, however, one class of uterine flexions productive of obstructive dysmenorrhœa. I allude to supra-vaginal flexions, where the angle or curve is above the vaginal portion. A flexion of the cervix only may be, and often is, associated with sterility; but even then, not always with dysmenorrhœa. This supra-vaginal flexion tends to obstruct the canal, just as any bent tube offers more obstruction than a straight or moderately-curved one. Clearly, also, the more solid the *uterine contents* are, whether they be clot or decidua, the more difficulty will they encounter in adapting themselves to the altered curves. Some of the opponents of obstructive dysmenorrhœa have likened the curve at the angle of flexion to the bend of a river which offers little or no opposition to the easy flow of the water, but if the river be narrow and the bend acute, a large semi-solid body floating in the liquid stream would find it difficult to get round the corner. The pain in obstructive dysmenorrhœa is due to the mechanical dilatation of the canal, and is directly proportionate to the resistance offered by the uterine tissues to the contents passed. This is well seen in membranous dysmenorrhœa, where, after some preliminary ante-menstrual pain of the spasmodic type, there may be an interval of repose, followed by severe pain, which begins gently, increases to a maximum, and then as each shred passes, dies away again almost suddenly. To ascertain the existence and exact position of real obstruction, whether due to supra-vaginal flexion, organic stenosis, or to other causes, a bulbous-ended bougie must be passed beyond the seat of stricture to the fundus, observing how far it enters, and how far it is withdrawn before the bulb catches. As the bulb passes through the constricted portion, the same pain will be experienced as at the menstrual period.

Fibroids, again, may cause obstruction by narrowing or twisting the canal, by favouring displacements; or may, by causing menorrhagia, tend to the formation of clots, which pass with difficulty. They may also cause congestion by pressure on the trunks in the broad ligaments. Occasionally, they cause irregular or inefficient uterine contraction, or acting as foreign bodies, may cause painful spasmodic contractions of the entire muscle.

Inflammatory Dysmenorrhœa.—When the pelvic organs become inflamed, whether it be endometritis, metritis, salpingitis, or ovaritis, we must expect either the arrest or the disarrangement of such part of the function of menstruation or ovulation as is respectively performed by them. It is impossible to here allude to these conditions in detail, beyond saying that both in acute and chronic inflammation the symptom—dysmenorrhœa—with which we are now concerned is only one of a group of symptoms, which differ according to the organ at fault. Chronic metritis is often the result of subinvolution, and is often present when least expected, its onset being insidious. Salpingitis is only now receiving due attention, one fairly constant early symptom being an intractable menorrhagia. Adhesive peritubal peritonitis causing interference with the peristalsis of the tubes, or constriction of their canals, also produces tubal dysmenorrhœa, which is said to be clonic in type, but of which nothing very definite is known. It is necessarily always associated with sterility if the occlusion is complete and bilateral.

Ovarian Dysmenorrhœa, or dysootocia, as Barnes has called it, is a very common and very painful form. The

term means that the process of ovulation is performed with difficulty and pain. It may either precede, accompany, or follow the menstrual flow. It is produced whenever the maturation or ripening of the ovum, with coincident enlargement of the Graafian follicle, is prevented by acute or chronic ovaritis, or by cirrhotic or other structural changes, and also whenever the ripened ovum is prevented from escaping by peri-oöphoritis having caused thickening of the fibrous or peritoneal coverings of the ovary. Amongst other frequent causes of dysotocia are ovaries which have prolapsed downwards into Douglas' pouch, either from congestion or early cystic change adding to their normal weight, or from falls, or superincumbent pressure, or from being dragged down by a retroflexed or retroverted fundus uteri, or contracting retro-uterine adhesions. One ovary only (usually the left) may be at fault, the other being normal and normally situated, producing dysmenorrhœa at alternate periods. The pain varies in character, being aching or shooting, and is referred to both the original and altered position of the ovary if prolapsed, and is accompanied with more or less coccygodynia, dyschezia, dyskinesia, dyspareunia, and bladder irritation. This form of dysmenorrhœa simulates that of acute ovaritis or peritonitis, the pulse running high from the nervous hyperæsthesia present, but the thermometer reveals no more pyrexia than is usually present at the onset of nearly every normal menstruation. Physical examination is difficult during the pain—so tender are the abdomen and pelvis, and so rigid the parietes; but after it has subsided, the ovary will be felt enlarged (unless cirrhotic), lying low, and exquisitely and characteristically tender.

Peri-uterine Inflammation.—In such cases, with effusion of lymph, serum, or pus, the pelvic organs are at first pushed away from their normal position, and as a rule fixed; but afterwards, as the effused material becomes absorbed, they gradually not only resume their position, but are often drawn over by the contracting adhesions till they occupy the position previously held by the inflammatory products, and, what is worse, may be fixed there. Thus the fundus uteri or ovary may be bound down to the bottom of the pouch of Douglas, or bands of lymph may constrict one of the tubes, or exert pressure on the venous trunks in the broad ligaments. What more natural than that dysmenorrhœa should result from the fixation of such viscera, whose contractile powers become hampered, their curves altered, and their circulation impeded?

Congestive Dysmenorrhœa may be primary or secondary. If *primary*, it predisposes to prolapsus. It may result from shock, exposure, or protracted fatigue, especially that due to pedal sewing machines when used at or prior to the menstrual period. *Secondary* congestion may be due to inflammation, fixation, or displacement of either uterus or ovaries, or to cardiac, hepatic, pulmonary, or renal disease, then merely forming a part of the general venous congestion, and, indeed, in such cases metrostaxis may relieve the whole system, acting as a safety-valve. The type of dysmenorrhœa here is inconstant as regards the kind of pain, but its being grouped with the signs characterising congestion make it distinctive. Sometimes the pain simulates spasmodic dysmenorrhœa, *i.e.*, ceases as soon as the flow becomes established, being then doubtless due to a temporary stenosis resulting from the swollen and engorged mucous membrane, which being relieved by the general oozing from its free surface, becomes less swollen, and allows free exit to the uterine contents.

(To be continued.)

INFANTICIDE: AN INQUIRY INTO ITS CAUSES, AND THEIR REMEDY.

BY FRANCIS VACHER, F.R.C.S.,

MEDICAL OFFICER OF HEALTH FOR BIRKENHEAD.

IN Addison's "Vision of Mirzah" is described the bridge of human life standing in the midst of the tide of eternity. "Innumerable trap-doors lay concealed in the bridge, which the passengers no sooner trod upon but they fell through them into the tide, and immediately disappeared." It was noticed also that "these hidden pitfalls were set very thick at the entrance of the bridge."

Under this beautiful figure attention is drawn to the uncertainty of life at all ages, and especially to its uncertainty among those to whom life is a new gift, and who should hold it firmly.

A simple child,
That lightly draws its breath,
And feels its life in every limb,
What should it know of death?

The question, "Why do little children die?" is one deserving of grave study. Let philosophers and physicians try to solve it! The answer is to be had for the seeking. The waste of infant life is enormously in excess of what one might expect in a civilized community. Year by year about a quarter of those who die in England and Wales are under one year of age; and the proportion of infantile deaths to births is upwards of fourteen per 100. And what are these infantile deaths ascribed to? The main causes as certified, or entered in the registers, may be grouped under the following heads:

Febrile Diseases.—Measles, scarlatina, diphtheria (including croup), and whooping cough.

Bowel Diseases.—Diarrhœa, gastritis, enteritis.

Lung Diseases.—Bronchitis, pneumonia, congestion of the lungs.

Convulsions.—Cephalitis.

Hereditary Disease.—Syphilis, scrofula, tuberculosis.

Premature birth and malformations. Teething. Atrophy and debility. Suffocation.

This classification is not strictly scientific, but convenient. Having thus the chief causes of the deaths of infants, let me briefly consider them. Are they preventable causes? Do they suggest neglect, or worse? Do any of them imply infanticide?

As regards febrile diseases, though the local authorities may do much to suppress them, or at least to limit their spread, the individual householder cannot bar them out, but he may often by careful treatment of a case prevent a fatal termination. Bowel diseases and lung diseases affecting infants are largely due to improper food and unwholesome water, to insufficient clothing, cold, and neglect. In the subjects of lung disease especially, the neglect is often so marked as to be the obvious cause of the malady, and inasmuch as the neglect continues till death, the parents or guardians of the deceased are constructively guilty of infanticide.

Convulsions I regard rather as a symptom than a disease. Deaths of infants ascribed to convulsions, cephalitis, and meningitis, are probably, with only a small proportion of exceptions, due to congenital taint, and might be grouped with deaths from hereditary diseases. Prematurity and malformation are doubtless sufficient causes of deaths, but the truthfulness of the record so far as premature birth is

concerned is discredited by the fact that this death-cause is so often not vouched for by any qualified medical practitioner. When it is duly certified, nothing is stated about the cause, which is often parental syphilis, or intemperance. A considerable proportion of the deaths of infants which take place during the period of teething are ascribed to teething. The prominent symptom is commonly convulsions, and there is little doubt that the primary cause of death is often hereditary disease.

Atrophy and debility, marasmus, malnutrition, inanition of infancy, are such general terms, that they are almost necessarily used as a ready cover for ignorance. Among uncertified deaths the favourite causes assigned by persons giving information to the registrars are debility, convulsions, and premature birth. The causes of so-called atrophy and debility are hereditary disease, improper food, starving, and drugging. The parents or guardians of many of the children whose deaths are referred to these causes are certainly guilty of constructive infanticide, or worse. The last of the chief death-causes of infants, according to the Registrar-General, is "suffocation." What does that mean? It means in most instances overlying—reckless mothers in the heavy sleep of intoxication smothering their babes. Infanticide, again!

What then are the ailments and "accidents" that kill (*i.e.*, the death-causes) during the first year of life? If one except the miasmata, malformations, a large proportion of the deaths ascribed to premature birth, and the results of cold catching, not always avoidable or remediable, they are mainly: 1. Hereditary congenital disease (syphilitic, scrofulous, or tuberculous). 2. Diseases and casualties, the outcome of neglect, ignorance, and wilfulness, or worse.

It is quite impossible to estimate with even proximate accuracy what proportion of the infantile mortality is due to hereditary disease, and what proportion to neglect, etc., more or less culpable. However, so large is the gross number of infantile deaths every year, that I am tempted to make a rough computation of the annual mortality from these two causes together. The number of deaths of children under twelve months old is about 129,000 a year. About 9,000 may be put down to miasmata; about 17,000 to premature birth and malformation; and about 24,000 to so-called unavoidable diseases. This leaves 79,000 due to hereditary diseases, or neglect, or both, many being obviously due to homicide—*e.g.*, a large proportion of the 1,400 deaths of infants annually ascribed to suffocation. It is to be noted also that nearly half the murders recorded are cases of infanticide—that is murders of children in the first year, generally in the first month, of life.

I should have preferred, as a basis to this paper, to have been able to state the number of deaths from infanticide for a series of years. Had I been treating of small-pox, or scarlatina, or measles, I could have given exact mortality statistics; but in the case of infanticide, just as in syphilis or intemperance, the recorded deaths are only a very small fraction of the actual deaths. I think, however, I may venture to affirm that no one who has studied the very poor, with the temptations and demoralising influences to which they are subject, will doubt that I have abundant warrant for my belief that every year, in England and Wales, the instances of constructive infanticide number many thousands, and the instances of deliberate infanticide many hundreds.

It is, of course, a painful reflection that so revolting a crime is no uncommon one. Still in this respect the

English are not worse than others. In some continental nations the crime is notoriously more prevalent than in England; and if we look to the East, or to barbarous peoples, we find infanticide is openly practised, or countenanced under conditions which often obtain. Indeed, in all ages and all lands the horrible sin of infanticide has prevailed. The nations of remote antiquity allowed it, so did the refined Grecian and the martial Roman. Travellers note that in China the exposure and drowning of infants is an ordinary custom among the poor. Infanticide is practised in Central Africa, among the aborigines in Australia, the islanders of the Pacific, and some frontier tribes of India and America. Indeed, so widespread is this crime, and so numerous are its victims, that it is reckoned by political economists as one of the checks to population. Those who desire its repression, so far as may be possible, which practically includes every humane man and woman in the community, will do well to study its causes. These I now propose to discuss. Some of the causes are common to many countries and periods; some obtain only in very limited areas, and for limited times. I purpose to refer to causes which are in operation in our own country at the present time, and to these alone. They are mainly five—viz.:

1. *Early Improvident Marriages.*—These, which many sensible people regard as deserving only of light censure, are for many a young pair the beginning of a downward career that ends in poverty, and squalor, and vice, and crime. It is gratifying, at least, to know that the mean ages at marriage are rising, and have been since 1873, when they were at their minima; but notwithstanding this, under-age marriages are still very numerous. Let me refer to the Registrar-General's returns for 1886 (the last issued). In 9,558 of the marriages in that year, in England and Wales, between bachelors and spinsters, both parties were minors. Under-age marriages appear to be most common among miners, textile hands, shoemakers, and tailors. At such callings boys and girls early learn to make a living, and so become independent of parental control. The home is often full enough, and the lads or lasses at work pay only from 1s. to 2s. a week apiece for lodgings, and "find themselves in everything." They spend their evenings as they like, and choose their own amusements and their own companions, so that their parents have no interest, pecuniary or otherwise, in keeping them. For them home becomes little more than a sleeping place, and not always a quiet place for that. It seems as if any change would be for the better, so a promise to marry is given to a chance acquaintance, met for the first time a few weeks before at a music-hall or in the street. Sometimes money for a little furniture is saved; oftener the furniture is got "on the hire system," or a start is made in furnished apartments. When the marrying in haste is over, the rueing at leisure begins. At first the joint earnings of the boy and girl are more than sufficient to provide food, shelter, clothing, and recreation; but if provident habits have not been formed, nothing is saved. Unless the young couple are exceptionally vicious or ill-tempered, they live in a fools' paradise for a few months. Then the wife has to cease work, and while the expenses increase, the income is reduced by nearly one half. Under the pressure of debt and difficulty the child-mother returns to her work, to the prejudice of her own health and her child's. Often before the first child is a year old there is a second, and the family and expenses increase year by year, out of all proportion to the income, even when the elder ones are old enough to work. How

is it possible that young parents in such circumstances should regard their family as other than a burden? The shop girl or mill-hand, if she can earn as well as her husband, can only do so by neglecting her house and her family; and if she stay at home, she lacks training for house work, and is a poor, thriftless housewife. When any of the children fall sick, she knows nothing about nursing, and she is not actuated by that earnest desire to save her child that gives the necessary knowledge to some mothers. The sick child is one of many, of too many, perhaps the weakling, and the mother is not stirred up to use all her wits, and fight death by inches for it. On the contrary, she is quite resigned to anything that may happen, and coolly tells the doctor, who blames her for sitting with folded hands, "If it's the Lord's will, perhaps it's best for the child and for me too." If this be not constructive infanticide, what is it? Yet what doctor, practising among the poor, that cannot call to mind scores of mothers of this type. Such a mother is as thorough-going a fatalist as any Turk, only she is under the delusion that she is a Christian.

And how is the evil of early improvident marriages to be dealt with? It has been suggested that the State should forbid the marriage of any man unable to furnish proof of his ability to support a wife and family; but no modern State is likely to do anything of the kind, nor is there much use expecting a remedy for such an evil in legislation. If it be possible to do anything in this matter (and who can doubt that it is possible?) it is by employers and the well-to-do generally keeping touch with the working people. From the time that lads and lasses leave school till they are of age, how little charge is taken of them! Some churches set an excellent example, keeping hold of their young people, and do a great deal to check improvident marriages. Some employers also recognise their full responsibility, and take a paternal interest in all whom they employ, especially the young. However, there is a large proportion of working lads and lasses, not especially wild or ill-disposed, who come under the influence of no church, and whose employers know nothing of them, or how they employ their time when they leave their work in the evening. After the day's dull round in the mill, there is a natural craving for recreation, and abundant amusement and exercise of a wholesome character should be provided, *i.e.*, libraries, reading rooms, concerts, gymnasia, etc. But in all young people there is also a natural craving for sympathy, and failing to obtain this sympathy at home, or from a master or mistress, they rush blindly into marriage, just to have someone to open the heart to. Now, if every working lad knew an educated man to whom he could come at all reasonable times for sympathy and counsel, and every working lass knew an educated, sympathetic woman to whom she could unburden her mind, and tell her hopes and fears, it seems to me the main motive for early improvident marriages would be removed. The friendship and confidence of artisans and factory workers is not difficult for a man or woman of tact and frankness to win; and such friendships are infinitely more blessed and useful to the educated than the vain friendship of modern society.

2. *Hereditary Disease.*—That this is one of the most important causes of infant mortality is universally admitted, but that it is also a common cause of infanticide seems scarcely recognised. A child is born, the subject of syphilis, or some form of tuberculous disease, instead of commending itself to parental affection by feeding and

sleeping well, and by its healthy appearance, it pukes, and cries, and lies awake, and looks ugly, pinched, and woe-begone. Whatever the mother gives it or does for it, it will not thrive, nay, rather grows worse; swellings appear in the neck, perhaps abscesses, ominous skin diseases begin to develop; the little body wastes, and the thin legs are always drawn up. At least one of the parents is unhealthy, and the child is the subject of mutual reproach between the parents, and of commiseration from neighbours. At first the exceptional care and attention such a child requires is not given, then it is more or less deliberately neglected; finally, it is scolded and ill-treated by day and drugged at night. When the child dies there is not even a pretence of being sorry for it, and the immediate cause of death, whatever the certificate may say, has been constructive infanticide. Of course it may be urged that of all cases of infanticide these are the least deplorable. From a utilitarian point of view, doubtless, this is so; but regarded morally, when a weak sickly child is slowly done to death by its parents, a lower depth of turpitude is reached than by the unmarried mother who, in a frenzy of shame, suddenly destroys her newly-born infant. There can be no direct remedy for this frequent cause of infanticide, for one cannot prevent the subjects of hereditary disease from marrying, even though the laws of great States, long passed away, furnish a precedent for such prohibition. The suggestion made for checking early improvident marriages is applicable. The influence of the educated over the poor, and the increase of education among the poor, will tend to make them less reckless in the matter of marriage, and, at least, teach the lad or lass having health and good character to look for health and good character when choosing a partner for life.

3. *Illegitimacy.*—Certainly a large proportion of the infants whose deaths are entered in the official register under "homicide" are illegitimate, yet these represent scarcely a tithe of the number who are killed or suffered to die because they are illegitimate. To an unmarried working woman, the burden of a child is so great as to be almost intolerable, and she is beset by temptations to destroy it. The first temptation is before the child is born, and often from the seducer, and there are herbalists and midwives, so-called, ready to perform any service for pay. Next there is the temptation of the illicit baby-farm, which Charley's Act has not succeeded in wholly stamping out. One sees advertisements now offering "the comforts of home" to a nurse child for three shillings a week, or offering to take entire charge of and adopt an infant, for some paltry bonus, not exceeding twenty pounds, which the advertiser no doubt thinks may be obtained from the seducer. That a baby-farm may be carried on for a long time without suspicion in a new house in quite a respectable neighbourhood I can testify from experience in my own district a few years since. Yet what is the unmarried woman who has to earn her own livelihood to do with an infant? It is rarely possible for her to keep the child with her at her work, for, probably, she works on her employer's premises—she is a mill-hand, a shop assistant, a domestic servant. The infant must be left to strangers, unless some near relative takes pity on it. Sometimes a young mother, rather than part with her infant, will leave her ordinary employment and earn a precarious living as charwoman; and if this fail her, all that remains for mother and infant is to beg, or starve, or go to the work-house.

FROM GENERATION TO GENERATION: A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.,
F.R.S.L., ETC.

(Continued from page 159).

Diseases of the Locomotive Apparatus.—In this group are included the rheumatic affections of the joints and muscles; also those other disorders generally associated more or less with rheumatism—gout, arthritis deformans, rickets, and mollities ossium.¹

In considering the influence of heredity on this group of diseases, I shall at once refer to that feverish constitutional malady known as acute rheumatism (polyarthritis rheumatica acuta) without staying to discuss how the progress of morbid anatomy, and the comparative perfection of our diagnostic methods, in these latter days, have restricted the domain of ancient "rheumatism"—a term which once denoted far more than it does now. I think I need have no hesitation in stating that a predisposition to acute rheumatism is distinctly and emphatically hereditary, and that it tends to run in families: indeed, some recent observations on the transmission of a predisposition to this affection, by Fuller, Lebert, Picot, and other authorities, prove incontestably that the inheritance of such a predisposition is of very frequent—if not of invariable—occurrence, in those cases which are not acquired. In the case of rheumatism, this inheritance, says MacLagan, seldom declares itself before fifteen, and is generally lost again after fifty. What is transmitted is not the disease, but a tendency to it—a greater or less liability to contract it: that peculiar condition of the tissues of the motor apparatus which renders them a fitting nidus for the propagation of the rheumatic poison. He continues, "That some peculiar condition of the motor system is handed down in rheumatism, we know. That this condition declares itself by a special susceptibility of the tissues of the motor apparatus to the action of the rheumatic poison, we also know—but more than this we cannot say—for in this, as in all other cases of hereditary transmission, we can only indicate, not explain, the fact." Acute rheumatism is one of those diseases, an attack of which so affects the tissues of the motor apparatus as to render them peculiarly susceptible to further and more aggravated attacks; so that, *cæteris paribus*, the more strongly the rheumatic habit is thus developed, the more potent will be the influence of heredity in its transmission. The real nature of the rheumatic poison is still *sub judice*; but whatever revelations science may yet make as to this interesting question, there can be no shadow of doubt that a predisposition to acute rheumatism is recognised by experience; also that this predisposition is indubitably and strikingly hereditary.

It may be regarded as an axiom that the more a disease is constitutional, the greater will be the influence of heredity in its transmission; we can, therefore, easily understand why there should be some doubt as to whether chronic articular rheumatism is hereditary or not, being essentially a local affection. Bearing in mind, however, the fact that the majority of those who suffer from it, have already in earlier life undergone an attack, or attacks of acute rheumatism, and that the former affection is almost exclusively confined to the latter half of life, it certainly seems as if it were a *sequela* of acute rheumatism (which generally attacks pre-

disposed persons), and if, as is admitted, this predisposition is transmissible, there seems no reason to doubt that to some extent, at least, a predisposition to this *sequela* may also be inherited. All constitutional affections, unless neutralised by circumstances, as marriage into a new stock, must be inherited in some form or degree; but it is not necessary that the inheritance transmitted to the child should be exactly alike, or assume the identical form characteristic of his parent. I have already referred to metamorphoses in transmission, which account for such facts as the scrofula of one generation becoming tubercle in a subsequent one, or cancer alternating with tubercle or scrofula: we must not on this account deny the potency and efficacy of heredity, which is the rule, however individual peculiarities may differ, but rather believe that, despite such metamorphoses and dilutions which we may not be able to understand or appreciate, the law of heredity is inexorable, and like all other natural laws its potency can never be lost. In this way we may account for the fact of a constitutional affection like acute rheumatism—or rather a predisposition to it—being inherited, whilst the effects of heredity are less potent as regards one of its local *sequela*, chronic articular rheumatism. That any one, however, who has inherited a predisposition to acute rheumatism, subsequently suffers from it, and later on in life develops chronic articular rheumatism, can in turn transmit a predisposition to the one, without, at the same time, transmitting some susceptibility to the other—however diluted or whatever form it may assume, I, for one, cannot admit. The one thing we have to remember is that heredity is the rule; that, however, it may be altered by circumstances in form or degree, its efficacy still exists, and this, notwithstanding the fact that we may not be able to recognise it. I therefore contend that chronic articular rheumatism being most frequently a *sequela* of acute rheumatism, and a predisposition to the latter being transmissible—that although the latter is constitutional and the former local, they stand towards each other as cause and effect, and consequently a predisposition to the one must include to some extent a predisposition to the other. In the same category may be included myalgia, lumbago, etc., which, whether dependent on inflammatory changes in the muscular or the interstitial connective tissue, or neuropathic conditions, are decidedly hereditary, as is proved by every-day experience. I have myself known families, members of which have suffered from attacks of lumbago in one generation after another, and we have all seen the same thing occur as to rheumatic cephalalgia, intercostal rheumatism *et hoc genus omne*.

In approaching the consideration of the heredity of gout, I am fortunately assailed by neither doubt nor difficulty, as in the vast majority of all cases of gout, it occurs in consequence of an inherited predisposition, and this is admitted by all authorities. Out of 523 gouty patients, Scudamore found that 309 had come from a gouty stock; Gairdner, 140 out of 156; Garrod 75 per cent.; and Braun, out of his sixty-five patients, did not find one whose parents or grandparents had not suffered from the disease. Dr. Garrod, in his classical work on "Gout and Rheumatic Gout," instances the following cases:—"A few years since, I was consulted by a gentleman labouring under a severe form of gout, with chalk-stones, and, although not more than fifty years old, he had suffered from the disease for a long period. On inquiry, I ascertained that for upwards of four centuries the eldest son of the family had invariably been afflicted with gout when

¹ Ziemssen, vol. xvi.

he came into possession of the family estate." He also relates the following case, which illustrates the terrible influence of heredity in connection with the disease now under discussion: "A gentleman, forty-eight years of age, whose health has been good with the exception of attacks of gout, which commenced at the age of thirty-six in one great toe. The attacks gradually became more frequent, and more prolonged, so that he was scarcely ever free from them." Dr. Garrod thus sums up the hereditary influence in this case: "The father had very severe gout, the mother, when seventy years of age, began to suffer from it; he has had six brothers, of whom one died of very severe gout, and was crippled from chalk deposits in both upper and lower extremities; another had severe gout and chalk-stones, and died of albuminuria; a third had gout and paralysis, of which he died; a fourth had gout, and died of erysipelas; a fifth died of gout, complicated with some urinary affection; and a sixth is alive, but suffers from gout in the same way as the patient himself." Gout occurs much more frequently in men than in women, who seldom suffer from it until after the menopause; the predisposition is, therefore, more frequently inherited from the father's side than from that of the mother; moreover the tendency may often be traced to the grandparents, while the parents themselves remain free, especially if they have been careful to avoid the exciting causes of the gouty attacks. Heredity also influences the time of life at which the gouty paroxysms supervene: thus, in those persons who have an inherited predisposition, the attacks come on at an earlier period than those who have an acquired tendency; in the latter gout usually makes its first appearance between thirty and forty, but in those hereditarily predisposed it may manifest itself at a much earlier period. Gout is not only a very serious malady in itself, but may become the parent of grave constitutional and functional disorders and diseases. Of these the following may be here enumerated—viz., of the digestive organs: gastritis, neurotic disturbance, dysphagia, intestinal colic, diarrhoea, and hepatic derangement; of the nervous system: headache, vertigo, mental disturbance, delirium, mania, epilepsy, neuralgia, cramp, local paralysis, meningitis; of the heart: slow, rapid, weak, irregular, or intermittent action, syncope, collapse, and various painful and disagreeable sensations; of the lungs: asthma, bronchial catarrh, and pulmonary congestion; of the urinary organs: chronic cystitis, urethritis, gravel, and calculi. In addition to the foregoing, there is also the terrible hæmophilia, now regarded as a result of gout; apoplexy due to rotten blood-vessels; and the cirrhotic, fibrotic, or gouty form of Bright's disease. In this extensive category might also be added eczema and various other forms of skin disease.

We thus see how compound and complex is the inheritance of gout in all its terrible totality! A typical case of gout, whether inherited or not, is easily recognised, and that it is generally hereditary is freely admitted; but when we see, as experience leads us to expect, severe digestive, nervous, cardiac, pulmonary, and genito-urinary symptoms developed in gouty subjects, we should regard them as revealing symptoms, and remember always that these, too, may be perpetuated hereditarily, either in similar or dissimilar forms, in accordance with the law of variability—one series of the phenomena of which is represented by the so-called metamorphoses in transmission. Taken either singly or together, all these symptoms reveal the gouty dia-

thesis which is strikingly hereditary, so that in their production heredity is always not only a potent, but an inevitable factor wherever they exist or may co-exist. No one who has ever suffered from gout is incapable, *ceteris paribus*, of transmitting a tendency to some of its protean forms to his children, and although in each case it may manifest itself differently, yet it should never be forgotten that heredity and variability are the two sources of the tissue proclivities which attest the inherited taint of gout in every case. Heredity, in fact, necessitates the transmission; variability is accountable for the degree and variety of the inheritance.

Rheumatic gout, or rheumatoid arthritis, may be said to bear the same relation to gout as chronic articular rheumatism does to acute rheumatism or rheumatic fever; although it may occur in persons who have never suffered from either gout or rheumatism, whilst generally presenting evidences of both, especially in its external characteristics. The pathology of rheumatoid arthritis is still a *questio vexata*. Dr. Fuller's views are as follows: "The disease should not be regarded as of a hybrid character, or, in other words, made up in part of rheumatism, in part of gout. It is my firm conviction that, just as true rheumatism and true gout do both manifest themselves at different periods of life in the same individual, so rheumatic gout may arise in a person who either has been, or may hereafter become, subject to true rheumatism, or true gout, and that it has no connection with either of these diseases, beyond that which attaches to it in virtue of its being a constitutional disorder, producing local manifestations in the joint." As Sir Alfred Garrod, however, naïvely remarks: "It is a much easier task to prove what rheumatoid arthritis is not than to give the slightest clue to what it is." Irrespective of its pathology, I am more concerned with the hereditariness of a predisposition to it; and although it must be admitted that the influence of heredity is less potent than in that of gout or rheumatism, yet I maintain that like all other constitutional conditions, however they may be modified in transmission, a predisposition to rheumatoid arthritis is transmissible, and this in the face of much opposition. Thus Garrod says: "Hereditary tendency does not appear to exert any very special influence; for in looking over the histories of numerous cases, I fail to find much evidence of its action; if it exists at all, it is much less powerful than in gout. We often find one member of a large family suffering severely from this disease, and the others entirely free from it." Now the great authority from whom I have just quoted does not deny that it is hereditary to some extent, but admits that the hereditary tendency is less powerful than in gout. I also admit this; but until the question is settled as to why some morbid affections should be so much more strikingly hereditary than others, we must be content with the fact that such is the case, and rely entirely upon the light afforded by an ever-increasing experience. That experience warrants our belief in the hereditariness of rheumatoid arthritis is evidenced by the testimony of Professor Charcot, who, in forty-one cases, found a hereditary predisposition well marked in eleven. Moreover, Garrod strives to strengthen his negative testimony as to the hereditariness of this disease by instancing the fact of one member of a large family suffering severely from it, while the others remained free! May I venture to ask if all the children of phthisical, scrofulous, or even gouty parents, have this predisposition transmitted to them in the identical forms, and in similar degrees, as those existing in the

parents? Surely not; else, indeed, should we be able to witness the realisation of the ideal law of heredity! The fact is that variability or atavism, however mysteriously, predetermines which children shall be affected, and in what degree, or whether, whilst they themselves may entirely escape, they may have the inherited predisposition enshrined within them, inoperative, ineffective, and inactive, so that they, in turn, may transmit it to their children, and their children's children. May I also ask, how came one member of the family, alluded to by Garrod, to be suffering from the disease? Did he inherit or acquire it? If the former, he will undoubtedly pass on a predisposition to it, more or less; if the latter, he may also transmit it, even in an aggravated form. Heredity works in larger cycles than we are apt to give it credit for; for beyond the parents and their children are their ancestors and their descendants for many generations, and even as the past slumbers in each one of us, so do the sanitary welfare and happiness of our children's children in the future, for heredity governs all, and its force is never lost.

When alluding to the rachitic diathesis, in an earlier portion of these papers, I said that authorities were divided as to whether it was hereditary or not, also that the majority seemed to think that it was not. At the same time I admitted my belief that the general condition of the health of the mother had much to do with a predisposition to rickets in her children, provided her health was low and poor. To this opinion I still adhere, although time and circumstances impel me now to favour the views of those who regard rickets as hereditary, whatever may be said as to the hereditariness of the diathesis. At least in numerous cases of rickets, hereditary influence has been a factor of great importance, especially manifesting itself in a predisposition inherited more frequently from the mother than from the father; moreover, it has frequently been observed that when several families have resided under the same roof, and under similar circumstances, none of the children became rickety except those whose fathers or mothers had suffered from rickets during their childhood. Besides, as a further evidence of an inherited predisposition, numerous cases of foetal or congenital rickets have been observed under circumstances which negated the possibility of any syphilitic or placental influence. As shewing metamorphoses in transmission, I may mention the fact that other constitutional diseases in the parents may contribute to the production of rickets in their offspring; thus Ritter von Rittershain alleges chronic tuberculosis in the father as a predisposing cause of some importance. Among the parents of seventy-six rickety children whose family history he investigated, he found seven tuberculous fathers and four tuberculous mothers. In the same way many facts are forthcoming to support the opinion that constitutional syphilis in the parents also predisposes to rickets in the children,¹ and thus heredity acts mysteriously and potently with variability, acts and interacts, preserving and perpetuating the commonhealth of the community, as it preserves and perpetuates the characteristics of the race by varying and differentiating the individual.

Of the remaining diseases of the locomotive apparatus, I have still to refer to that very rare disease, osteo-malakia or mollities ossium, which has also been termed "rickets of the adult." Alluding to this, Mr. Hutchinson says—"Respecting a certain number of the best marked cases, there appears good reason to believe that the disease is really a form of

rickets, and that the differences observed between the two maladies are chiefly due to the very different condition of the osseous system as regards its development at the time of attack." Facts are forthcoming which support this view; thus Trousseau records a case in which osteo-malakia attacked a woman of seventy, who had been rickety in childhood. Mr. Hutchinson also mentions a case (the skeleton of which is in the Brighton museum) where the man had lost two feet of his stature from innumerable fractures, faulty union, and the bending of his bones. The children of this man were much deformed by infantile rickets. As to the identity of osteo-malakia with rickets occurring at a later period of life, and the heredity of both, with regard to the former it should be remembered that the rachitic diathesis is dependent upon defective diet and absence of warmth and sunlight; that, as a general rule, it is only temporary, existing no longer as soon as the defective surroundings and diet are supplanted and neutralised by warm, dry, pure air, sunshine, and judicious dietetic treatment. Yet it is probable that in the few rare cases of mollities ossium which occur, it may have been reproduced, or developed *de novo*, under circumstances similar to those on which its primary production depended. Be this as it may, there is much in common in rickets and mollities ossium for which the rachitic diathesis satisfactorily accounts; and when we remember that both spring from and are perpetuated by constitutional conditions involving defective nutrition, we need have no hesitation, especially in the light of the affirmative evidence recorded, in regarding both affections as transmissible by heredity.

HEALTH RESORTS OF THE WORLD.

XIX—ILFRACOMBE.

BY DR. ALFRED J. H. CRESPI, OF WIMBORNE.

THE misguided mortal who allows himself to be over-persuaded to write descriptive papers on "Health Resorts" seldom finds his task pleasant. If he ventures to criticise, however kindly and fairly, he is sure to offend the residents, while if he praises warmly, and perhaps even permits himself to go rather beyond what his better judgment warrants, he only succeeds in overlooking some local lion to which residents attach undue importance, and so, instead of gratitude, he receives censure. A well-known medical writer puts this capitally in a racy letter he wrote me not long ago, from which I take the following lively passage; may my description of Ilfracombe not subject me to the unkind criticisms of the citizens of that flourishing little health resort:—

"I once assisted an old hospital chum, who had settled in practice in a flat (flatter, I never saw) district of East Anglia. In his occasional letters previous to my visit, he regularly urged me not to be carried away by the popular idea that the locality was flat. Arrived at the nearest railway station, I found no vehicle could be had, and the day being fine I walked some four or five miles. At one part of my walk I enquired my whereabouts, and was told that I was on *Turner's-hill*. Up to that moment I was absolutely unconscious of any rise in the road. However, I did imagine a slight drop, say of eighteen inches per mile—for the next three miles to where my friend lived. In the evening, he (having been out visiting when I arrived) mounted his hobby horse, and

¹ Senator.

remarked that though the site of his house was rather low, he would drive me on the following day to some more elevated positions. It was hard to control my risible emotions when he suddenly pulled up his horse on Turner's-hill, and bade me feast my eyes from that elevated spot upon the surrounding country. Never till then did I thoroughly comprehend the term 'relative' as applied to different men's ways of estimating things."

On the north-west corner of the county, picturesquely situated on a bold headland, a dozen miles north of Barnstaple, and forty north-west of Taunton, stands the quaintest and most charming of the many beautiful watering places of Devon. Ilfracombe, what music is in the name! is every day getting better known and more appreciated. Its isolation—in part from the remoteness of that portion of the county, in part from defective railway service—is being got over, and before long will be a thing of the past. From Bristol in summer, and from Swansea, at any rate at that pleasant season, Ilfracombe is easy enough of access. But Bristol and Swansea are a long way from Manchester and London, and though steam has practically annihilated time and space, at least so people say, we slow moving Britons don't like the thought of a journey of 200 miles or more. Once, however, that the lovely valleys and pretty hills of Devon are traversed, the visitor has no cause to complain.

Two railway routes have been opened to Ilfracombe—the London and South Western, *viâ* Exeter, and the Great Western, *viâ* Taunton; both are charming, particularly on a summer evening, and whichever way he goes there will be more than enough to interest the visitor.

The town is quaint and rapidly improving, and has many noble villas in the suburbs, and numerous excellent shops. The railway station is curiously perched on the top of a lofty artificial embankment, high above the town and some little way from it, and every year new houses spring up of all sizes, and there are other unmistakable signs that the town is fast encroaching on the country. Ilfracombe, though with undoubted a most brilliant future before it, is still small, its population hardly exceeding 7,000. More exactly, the estimated population to the end of last year was 6,650. The number of births registered was 169; this is equal to a birth-rate of 25.4; and the deaths were 98, equal to a death-rate of 14.7. The deaths of ten visitors were included among the latter, so that the death-rate among the stationary population of 6,650—or in other words, the true death-rate for the last twelve months—was 13.2. In the season the influx of tourists amounts, it is said on good authority, to the enormous total of 200,000. One of the most notable features of the place is its rocks—bold, precipitous headlands, from which extensive views over sea and land are got. In the far distance, on the western horizon, a faint ridge is visible, that is, the interesting little Island of Lundy, still remaining one of the wildest and most romantic spots of the far west; while to the north is seen, in clear weather, the land of the ancient Cymry, that strange and excitable race, so touchingly attached to their beautiful mother tongue, a people once almost exclusively dwellers in the open country, on the bleak hill side, and in lonely moorland farms, but now changing their habits and pouring into the towns, where they nevertheless retain many characteristic features of their ancestors, such as their hearty religious worship, their fierce enthusiasm, and their musical mother tongue.

The singular mildness of the winter climate, and the coolness of the summer days, are bringing Ilfracombe into

marked prominence as a Health Resort. Kingsley wrote:—"If you are sea-sick, or heart-sick, or pocket-sick either, there is no pleasanter or cheaper place of cure (to indulge in a puff of a species now well nigh obsolete—the puff honest and true) than this same Ilfracombe, with its quiet nature, and its quiet luxury, its rock fairy land and its sea walks, its downs and combes, its kind people—and if possible—its still kinder climate, which combines the soft warmth of South Devon, and the bracing freshness of the Welsh mountains." Invalids, particularly those suffering from lung affections, are finding out that they are especially comfortable at Ilfracombe during the winter, and on days, when in the midland and northern districts, they would be confined to the house, at 'Combe they can safely and agreeably pass hours in the open air. On those dull, grey days, of which they get so many in northern towns (days of gloom, calm, and depression), at Ilfracombe the warmth of the sun disperses the cloud canopy, or, more accurately, does not permit it to form, and the bright sunshine, blue sky, and soft atmosphere remind one forcibly of an April morning elsewhere.

In the summer excursions often cross from Ilfracombe to Lundy and Clovelly: sometimes, too, a swift moving steamer ploughs the stormy waves and goes right round the bold rocks of Lundy—rather a long sea journey for one day: amply repaid, however, by the noble spectacle of the huge walls of rock on the west and north sides of the Island.

Among the most majestic sights of the south-west coast of England is the tremendous sea that after storms bursts upon the rocks. Strange, too! sometimes when the sea is raging and heaving like an unruly monster, and the largest ships toss like walnut shells, the sky and air are clear and brilliant, and visitors have the delight of basking in warmth and sunshine, and at the same time of looking down upon a turbulent ocean, magnificent in its fury, and irresistible in its power. Let no one leave Ilfracombe without seeing the Morte Stone, the Death Rock of the Normans, or let him ever after hold his peace as to his knowledge of the wonders of 'Combe and its romantic surroundings.

The Rev. G. Tugwell writes:—"People in general like Ilfracombe because it is different from most other summer seaside haunts: because it has no esplanade or reach of sand, where every-body must of necessity walk up and down if he walks anywhere: because there is a wide seaside walk at some distance from the lodging-houses, for those who like to enjoy sea air and sunshine without fatigue: because there are innumerable walks in all directions for those who like walks, and do not care to meet "everybody" in such proceeding: because one needn't always wear fine clothes, but may ramble about over damp rocks or dry cliffs unobserved but not unobservant: because from the very configuration of the ground it is one of those rare places, which man cannot utterly mar, however much he may try and has tried so to do—the houses must be built in detached groups, and in irregular lines, roads and paths must serpentine and rise and fall, and even the most rectangularly minded of architects and land surveyors cannot ruin the picturesque by straightness and regularity: because the climate is not one of extremes, for it is never too hot in summer, and rarely too cold in winter. The grass is green and sheltered; trees and shrubs grow, and flowers bloom even at Christmas time, as they do not in colder districts: because the ground is dry and the air moist, and one's body and mind are, therefore, invigorated and braced without being chilled and withered, as they are in less genial latitudes: because in fine, there is

more freedom and more health to be enjoyed here than in most other resorts of the kind."

Lodgings abound, and are cheap and of excellent quality. There is, moreover, an entire absence of that town air and noisy confusion that make some watering-places only second editions of London. Except for occasional sea excursions, Ilfracombe is not a particularly good centre for seeing many places of interest, although it has some of great beauty near, among others Lynton and Lynmouth, both so charming. Where, indeed, would you find, even in England, even in pretty Devon, anything sweeter and more characteristically English than the valley near Lynmouth on to Watersmeet? Excursion breaks and coaches run daily in "the season" between Ilfracombe and Lynton: a coach also plies between Ilfracombe and Barnstaple, and, though I only speak from hearsay as to the beauty of the latter, the drive has great charms. The excursion to Lynton is deeply interesting, and near Parracombe there are to be found wild wastes, strongly reminding one of Dartmoor and Exmoor, not merely magnificent, in their utter solitude and desolation, but withal interesting and most refreshing after the worry of town life. The wild uninhabited Forest of Exmoor is not far off, and it is a singular sensation to an Englishman to walk eleven miles along a highroad, not passing a single house. Yes, Ilfracombe is very beautiful, and highly favoured by nature and art, although, and most fortunately, it lacks the vast crowds of Brighton, and the noisy confusion of Ramsgate and Margate.

The subjoined extract from the *Christian World* is worth reproducing:—"Ilfracombe in spring is beautiful, with its lofty rocks looking warm in the golden sunshine, and its blue waters—ever alive with steamers and sailing ships—bounded on the west by Lundy Island. It is difficult to describe the picturesqueness of Ilfracombe. I should say if you took a bit of Malvern, and half-a-dozen Plymouth Hoes, and threw in a little touch of the inner harbour of Douglas in the Isle of Man, dotted over the green hill-sides and valleys no end of modern sea-side residences, and added a mile, in the shape of a High-street with old-fashioned shops, now and then intermixed with others of a later and more ambitious character, you could frame for yourself a pretty fair idea of the Ilfracombe of to-day, a place very much improved since Jane Taylor used to come here all the way from Ongar for the benefit of her health. As a winter residence Ilfracombe possesses many advantages. *Vanity Fair* the other day offered a prize as to the most beautiful county in England, and the loveliest watering place; and Devonians will be glad to hear that their county was considered the most beautiful in England, and that Ilfracombe stood highest on the list of towns, having obtained thirty more votes than Scarborough. Bournemouth secured the third place, Torquay the fourth, and the remainder were placed as follows:—Clovelly, Lynton, Lynmouth, and Hastings."

In a few days the lanes and hedgerows of Devonshire, already putting forth the promise of the summer, will be one mass of hawthorn blossom; the banks in many districts will be literally carpeted with splendid violets and primroses, and the tall and graceful elms will be donning their bright green summer dress. Then, in my opinion, is the time of all the year to visit Devon, and enjoy its glories. After all, the latter part of April, May and June are far more beautiful than August and September. The days are longer and brighter, the skies less cloudy, the foliage fresher and greener,

the songs of the merry birds far more continuous and inspiring, and the flowers much more plentiful. It is a mistake to put off the summer trip to the country until autumn is at hand or actually come. Early summer is the time to visit the country, and of all parts of England, none surpasses, perhaps none approaches, the villages and woods of Devon on a cloudless May day, and no watering places have greater attractions than those of the northern and southern coasts of that extensive county. I have seen Exmouth bathed in sunshine and clothed in rich verdure on an April day, and Exeter looking like a garden of Eden on the 28th of that capricious month.

The season at Ilfracombe is at its height in August and September, but on medical grounds there should also be a winter season, when invalids, rather than pleasure seekers and holiday folk, should go there in large numbers. Compare the weather in January at Ilfracombe with that at Walsall or Sheffield, recall the bright sunshine and soft balmy air that often make December and January pleasant enough on the Devon coast, and then ask whether the inland manufacturing towns have anything similar to offer. Assuredly not. When the improvements now in progress—the Winter Gardens, new piers, and Palace of Health—have been carried to a successful issue, they will add largely to its beauties and conveniences. 'Combe will then have nothing to fear from the superior attractions of any other health resort. The following meteorological tables will be useful, and figures are the best of all arguments, and the most convincing of all proofs:—

ILFRACOMBE SHADE TEMPERATURES, 1886.

1886.	Mean Temperature.	MEANS.			EXTREMES.	
		Maximum	Minimum.	Range.	Maximum	Minimum.
January	40.7	44.5	36.8	7.7	51.2	30.3

XX.—NOTES ON MADEIRA AND THE CANARY ISLES.

By ROBERT R. RENTOUL, M.D.

WE left Liverpool in the latter end of November by the British and African Steamship Co.'s *Opobo*. As we steamed off from the landing stage, on the tender, a keen bitter wind—rendered more biting by the frequent showers of rain and sleet—made us long for the far away and pleasant

sunshine of the Canary Isles. Outside the bar—the wind being strong and the waves high—Captain Clancy thought it well to put into Mulfra Bay. Here we remained at anchor all night, the holding ground being good, and the shelter perfect. Beyond, the waves were big and white, while inside, we, with about thirty other ships, lay in calm water. Invalids who wish to escape from this cold wind should start some time in September or October. Next day we proceeded on our voyage, and when near Holyhead our pilot left us. The usual ship routine, as far as we passengers are immediately concerned, goes on from day to day—sleeping, eating, a little reading, with perhaps a game of cards or quoits, a few songs at the piano, or a sweepstake of a shilling contribution from each, on the distance run (the half going to the Sailors' Home), make up our daily life. Coffee and biscuits are on the table at 6.30 a.m., breakfast at 8.30, lunch at 1, afternoon tea at 4, and dinner at 6.30. The food, as far as material goes, is very good, but more attention might be given to the cooking. There were too few stewards—one to each table at which twelve persons sat not being enough. The stewardess, by looking after those sick in bed, helped to lessen the difficulty. One must remember, however, that this line give a round-trip ticket, lasting twelve months, for £15. Some of the vessels have a smoke room, and their saloon amid-ships.

Our voyage through the Bay of Biscay—or to be more accurate, our voyage along the edge of the bay, for we scarcely enter it—was pleasant. I have crossed the bay on twelve occasions, and never yet had rough weather. No doubt, however, of its being rough sometimes! Each twenty-four hours brings us into warmer latitudes, the thermometer gradually rising. On the morning of the seventh day we arrived at Madeira, and anchored off Funchal. Before reaching this island, we passed the Desertes—three barren rocks, which are not inhabited, except occasionally by fishermen and turtle seekers. The Loo Rock and the lighthouse, near Funchal, as well as the coast line, look attractive. The Health and Customs authorities having passed our ship, many boats pull off from the shore with fruit, Madeira chairs, and other wares. Native boys cast off their scanty clothing, and invite the passengers to throw "one shilling" or "one sixpence" into the water, for which sum, or less, they will give an exhibition of their swimming and diving powers, some even offering to go under the ship and come up at the other side. This is a variety of entertainment seen in many warm latitudes, as Suez and Sinagapore. We then made a start for the shore. To land here is sometimes a difficult matter, especially when the wind blows in on the shore. However, the boatmen—who engaged to take us for one shilling each—knew their work, and so we trusted to them. As we neared the shore the boat was pulled round, with her head to sea. We next drifted slowly in; and then, waiting for a fair-sized wave, we rushed in and grounded on the beach. This is the signal for two of the boatmen to jump out into the water, where they steady the boat. Another wave is waited for, and with a helping hand from those on shore, the boat is pulled up high and dry. One word of advice may be necessary for the nervous. Sit quietly, and sit low in the boat, and do not rise from your seat until told to. It is a pity the Portuguese Government does not see its way to build a mote or a break-water here. Having landed, we may either walk, ride, or drive to the hotel. We preferred going in a bullock cart. This vehicle is somewhat like a sledge; it is covered in by

a top and side awning. Two quiet oxen pull it along over the large flat stones with which the street is paved. One man goes in front and guides the bullocks, while the other, with an oiled rag, runs along, now and then placing the latter under the runners, so that it may glide more gently over the stones. We stopped at one of Mr. Reid's hotels—the "Santa Clara"—and ordered lunch and dinner, as the captain had told us we need not come off until eight o'clock. This hotel is well situated, and has a good garden, verandah, tennis court, and billiard room. The charges vary from 8s. to 10s. per day for one person, but other arrangements can be made by those who propose remaining for some months. We paid 3s. each for lunch, and a little over 4s. for dinner.

After lunch, we engaged hammocks, and went up to the church on the mountain, this building being placed at an altitude of 1,800 feet. These hammocks, borne by two men, are very comfortable. Each bearer carries a stout, short pole in one hand, having a fork-like termination at one end. This he uses at one time as a help in climbing, while at another he places it over the shoulder unoccupied by the hammock-pole, passes it under the latter, and with his back as a fulcrum, transfers the weight from one shoulder to another. Now and then the men rest; when one end of the hammock-pole is placed in some convenient hole in a wall, while the other rests in the fork of the staff. The bearers perspire profusely. They have strong tendencies to stop at all the wayside inns, here asking us for money to buy some wine. I have been told that it is a mistake to give them anything until the journey is completed, and also that they do not at all appreciate one's getting out to walk, so as to rest them. We climbed up the steps of the church. Here there is a beautiful view of Funchal, the bay, and the neighbouring mountains. Having seen the church and bought some crochet work, we arranged to come back. It is the custom to come down from the church to Funchal in the carro, or running sledge; but one of our number was timid, so we took the hammocks back, and returned by another way. The carro-ride is spoken of as being most enjoyable. The carro consists of a kind of cane basket, fixed on runners; it whirls one rapidly along, and is not at all dangerous, though the streets are narrow and the turnings somewhat sharp. Two men stand behind, and with a rope guide it along. If they wish to slow down, one foot is placed on the runner, and the other on the ground.

Having arrived in the town, we took a walk through the streets, buying some articles of local interest. We visited the fruit market, and bought fresh figs, oranges, guavas, mangoes, and custard apples. The last-mentioned fruit is very luscious; it is cut into two parts, and the contents eaten with the aid of a spoon. We also called at the hospital. The resident surgeon kindly showed us through the wards. One patient was suffering from typhoid, and several from consumption. On the outer wall of this building is an aperture, guarded by a small door. Inside this is the place where mothers who wish to forsake their infants, leave them. On doing so, a bell is rung, when a sister comes and takes the baby. Afterwards, it is given to a wet nurse, and if not hereafter claimed, it belongs to the Government, who educates it. I was told that this system of disposal of infants does not in itself lead to any increase in the number of illegitimate children, and that on an average about thirty are put in each year. A similar system is in force in the other islands, in Spain, and other European States. One would not like to see such a form of vice legislated for in

this fashion, and introduced into England, although it might seemingly lessen the infantile mortality. But it is to be remembered that the death-rate of all foundling hospitals is excessive. The hospitals in these islands are supported by State taxation, and not by a system of charitable benevolence, as at home. They resemble more in appearance our best workhouse hospitals.

Having dined we went on board, regretting we had not a few days to spend here. Those who go ashore with luggage have to pass through the customs, as they examine and tax almost everything. Even a tax of 13s. 6d. is put on anyone who remains on the island over one week. Funchal is a beautiful and picturesque spot. There are many mountains to climb, and the trips to the Gran Corral, and the Twenty-five Fountains, as well as other places of interest, make the time pass pleasantly. There is an English doctor of medicine resident here; the hotels are good, while steamers and telegraph connect it with Europe. Many English reside here. The natives give one the idea that they are underfed, while their taxes press heavily upon them. The place seems to be very destitute of good level roads for walking and driving purposes, and invalids must soon tire of hammock, carro, and sledge. The horses are said to be sure-footed. The constant climbing must be a great effort to delicate persons, while the various temperatures experienced while ascending and descending may be productive of chills. It is well, therefore, when climbing to take rugs. Funchal has a heavier rain-fall than the other islands; this, and its dampness, being the chief objections. The net humidity of Madeira is said to be 76°, while that of Orotara is 64.9. I am told that it is much pleasanter and healthier living in a private house, than down in Funchal, with its narrow streets, where there is less pure air and sunlight. From October to May is considered to be the best months to spend here. *The Castle Line* of steamers (D. Currie and Co.) despatch steamers every alternate Wednesday from London, and from Dartmouth on the following Friday. These call at Funchal and Grand Canary alternately. First class fare out is about £14, and the homeward fare £12 12s. *The Union Line* from Southampton and Plymouth fortnightly, call at Funchal on both the outward and homeward voyages. The fares, first class, to and from Madeira are £15 and £12, respectively. Some families, it should be mentioned, engage a villa or kinta, situated at various heights on the hill. The rent of these vary from £50 to £200 for the year. But the local agents of any of the Steam Ship Companies would be willingly to give any information beforehand. Messrs. Forwood Bros. & Co.'s steamers leave London monthly. The fare to Grand Canary is £10 single, and £15 return. The fare for the round trip is £20. These steamers call at Madeira, Las Palmas, Santa Cruz, Orotara, Palma, and occasionally at Lauzarote, touching at Lisbon often on the voyage home.

From Funchal to Santa Cruz—the chief town of Teneriffe—is about 260 miles. On approaching this island we looked for the famous Peak, but as the clouds enveloped it, we could not get a glimpse of its snow-clad summit. Having remained a few hours at anchor in the bay of Santa Cruz, and taken on some more passengers, we started for Las Palmas—the capital of Gran Canaria. From port to port is about sixty miles, and we enjoyed our good luck in making the trip during day-time, consequently we had good views of the coast, the Isleta with its lighthouse and signal station, and the town and port. Passed by the port

authorities, Mr. Quiney, who owns the English hotel here, came on board and kindly offered to look after our luggage, and to take us on shore. As the hotels are generally full, it is better to engage the rooms by letter, or to telegraph from Santa Cruz, or Madeira. Hotel managers out here complain that many engage apartments and never come out. This may be so; but it is no excuse to offer to another person when he comes out, but finds his rooms occupied by some one else. The shore-boats are large, stoutly built and fairly dry. Our boatmen seemed to be afraid, as it was blowing a fairly stiff breeze. They say, "Mucho tornado;" but I think this was for our benefit! Having landed, we got into a coach, drawn by three horses, and off we galloped along a level road, for about three miles, to Las Palmas. The boat and carriage hire were charged in our hotel bills, so the visitors need not trouble himself with the boat men. No doubt, they will come up and ask for extras, but if people will give away money unnecessarily, they must take the consequences, and make the place disagreeable for subsequent tourists. The boat hire, coach, and conveyance of luggage, cost about four shillings for each of us. It is a pity the different Steamship Cos. do not agree to provide a steam tender; but here, as yet, no thought seems to be taken for the weak invalid. If he can rough it along with others, well and good; if he cannot, he must abide the results.

Quiney's hotel is situated in the town. The hotel is comfortable; the drawing room and dining room are of a fair size, but the latter is too near the kitchen—with the result that the smell of cooking is disagreeably prominent. The bedrooms are large; the beds extremely clean and comfortable, while the mosquito net protects one from the bites of these troublesome little animals. There is a billiard-room, a garden, and verandah. A tennis court is wanted, while a shooting gallery, and a croquet court are much longed for. Croquet should be the pleasantest game for invalids, as the lightning speed of the present tennis player seems almost to well-nigh ruin this deservedly popular game. The hotel charges vary from eight to ten shillings per day; but different rates are given to those who remain for some time. We slept at the Dependence, the best bedrooms here being pleasant and quiet. All have their meals at the hotel, which is about two minutes' walk from the Dependence. Hotel life here is quiet and calm. Our Spanish waiter, Juan—pronounced wan—brings in a cup of coffee and banana at about 7.30 a.m.; then a bath and dress; breakfast at 8.30; lunch at 1; afternoon tea at 4; and dinner at 6.30, coffee being served in the dining room after. The food is very good, but the mutton is usually tough. Excellent milk may be had for two or three pence per quart—a point the invalid will appreciate. Good porridge, fish, eggs, chop, steak, omelet, tea or coffee, and fruit are supplied for breakfast. The lunch is substantial, and the same may be said of the dinner. Native wine is also supplied free at dinner, but my advice would be, not to drink it. It is said to contain a fair quantity of potato spirit. There is rather a dearth of waiters, with the result that the intervals between the courses are too long.

The sanitary arrangements are fair, and the water supply good. One notices the absence of a weighing machine and such other trifles, appreciated by the invalid. An unpleasant feature—more especially for ladies and children—is that the bar of this hotel is close to the verandah and garden. Occasionally people come from the port and here imbibe

too freely. The presence of two large barrels of beer, with taps attached, and tumblers ready, do not add respectability or beauty to the place. Indeed, it would be an easy matter out here to ruin an hotel by sending a number of roughs—English or others—to drink, and make themselves unpleasant to the residents. One never sees a Spaniard suffering from any form of alcoholic poisoning. Alas! like a self-righteous race, we too often point to the faults of these Spaniards, while we fail to notice our own. Perhaps, in the near future, all these small, but eminently unpleasant—because so prominent—inconveniences will be removed. Mr. and Mrs. Quiney do all in their power to make their visitors comfortable. Perhaps the invalid, and those who cannot look after their own particular wants, are not so well off, but the scarcity of waiters renders it impossible for all to be looked after. Moreover, this is an hotel, *and not a hospital*. Certainly an invalid would not be taken into a London hotel if he required separate attendance, with his meals served in his bedroom, unless he paid considerably extra, and had a nurse with him. I feel certain that weak invalids, unable “to take things as they come,” should never leave, or be sent from, home, without a companion to look after their wants, and to provide any little extras. Would it not well repay a good nurse to live at Las Palmas, so that she might look after invalids at the hotels? At present there is no such arrangements, and the authorities at the Spanish hospital will not send out their nurses. Could they not be induced to do so?

The other hotels at Las Palmas are Spanish, and their charges are about four shillings per day. The disadvantages of eating Spanish cooked dishes, and being waited on by Spaniards who don't speak English, are sufficient to make one prefer to stay with those of our countrymen who provide for the wants of the traveller here.

The town of Las Palmas has a population of about 16,000, and to the tourist contains many places of interest. The cathedral is a fine building, and with its vestments, altars, and pictures, is well worth a visit. It is a good climb up the spiral stairs to the roof, but the fine view from it of the town and bay will well repay a little expenditure of energy. Up here one notices a bee-hive, the busy toilers enjoying themselves in the bright sunshine on this December day. The cathedral is not yet perfectly finished. Opposite it is the public square, which is provided with seats, while at the other end is the museum, containing so many interesting relics of the people who inhabited these islands, and who were exterminated some 300 years ago by the Spanish conquerors. Are we repeating history in our actions towards the natives of Australia, the Maories in New Zealand, the Red Indian in America, and the black man on the African coast, with our best gin *at two-and-six a case*? This museum, among other things, contains a jar of butter 400 years old, a few Guancho mummies, skulls, and bones; other parts are devoted to natural history specimens. A short walk, passing on our way a fountain at which the women draw off water by the aid of long bamboo rods, and by the Spanish hotel, brings us to the new theatre. This is an imposing building, and is now almost completed. Under the same roof is a concert hall, where, on the evening of our day of landing, we had the pleasure of being present at a really enjoyable concert. A walk along the main street and past the offices of the British and African Steamship Co. brings us to a garden provided with good trees and seats. It is called *el plaza de los Ingleses*. Opposite it is the new

house for the Governor. Beyond the garden a little way is the mole. It is unfinished, and will remain so. At it the coasting schooners land their cargoes. During the morning hours a pleasant walk may be taken here, provided no unpleasant smells are in the air. The fruit and fish markets are clean and also modern in construction. The streets are rather uneven, but the footpaths are smooth. A water-cart has, owing chiefly to the efforts of Dr. M. Douglass, been provided. Many visitors buy shoes made of goat skin; these cost about twelve shillings, being cool and light. One can walk about comfortably with clothes such as are worn during an English summer. A straw hat, a white-covered umbrella, and a pair of tinted glasses to counteract the glare will add to the comfort of travellers. The sanitary arrangements of the town are not very good, one meeting with very unpleasant smells. In fact, the manner by which the sewage is disposed seems to most people to be a mystery. The banana trees secure a full share. This, if allowed to go unchecked, must soon have a bad effect on this place as a health resort. The water supply, however, is very fair, and is brought from the mountains. There is an absence of English filters, but the “drip stones,” made from a porous sandstone, and which act as filters, take their place. I fear many look as if they had been too long in use, and remind one of some of our filters seen at home—these having been so long in service, and never cleansed, in reality, dirty the water which they are intended to filter. Does the invalid, with his little black respirator, never think how, often in long use, he breathes on it, and then asks it to let in pure air?

Visits may also be made to the casino, or club. It contains a reading, billiard, and ball-room, and is situated near the Plaza de Cairasco, where there is a statue to the poet Cairasco standing some little way in front of the main entrance of the old theatre. This theatre is under the same roof as the club. The members, in the cool of the evening sit out in front. During our stay they gave a dance, issuing a general invitation to the visitors at Quiney's and the Spanish hotel. At these dances there are no programmes, and it is not considered the “correct thing” to take a *senorita* out of the ball room to the balcony or stairs between the dances. The barracks, formerly a monastery; the *calegio* de San Agustin; the hospital, gaol, cock fight pits, the leprosy hospital, and the Spanish cemetery should be seen. A visit to the last mentioned place is, I am told, not of a pleasant nature. The bodies are placed either in graves or in holes in the walls. These tombs are let at eight shillings a year, and if this sum be not paid regularly the body is taken out and thrown into a corner of the cemetery. I am told that few Spaniards accompany their deceased relative's funeral. There is now a small English cemetery.

The beggars here are in great force. They are given one day each week, and some of them look miserable objects. Their cry of “*Deme un quarteto*,” soon begins to irritate one. They even come into the main passage of the hotel, and as they are covered with vermin, and suffer from skin and eye diseases, it would be much better if they were excluded. Perhaps the Spanish custom of each house supplying one beggar with food or money is a good one, and stimulates private benevolence; but to visitors the beggars are a great nuisance. Indeed, no one will regret taking a tin of Insect Powder with them, for one may be troubled with unbidden guests. Eye complaints appear to be very prevalent among the children. There are not many “*curios*”

worth buying. Certain old coins, called tostones, are made into bracelets, pins, and necklets. They have been made by dividing a dollar-piece into four; this action being due to the fact that the Spanish Government would not supply the island with a sufficient coinage! Crochet work of all patterns may be bought at the hotel, when Mrs. Quiney will tell one what to pay.

The evenings and nights are usually very fine. The night watchman, or sereno, with his long spear and bull's eye, calling the hours, makes an interesting picture. The streets are lighted with oil-lamps, coal and gas being absent on this island. Report says that the electric light will soon be introduced. Numerous barbers' shops are seen, while many people in the shops play cards, and so pass away the hours. Above the town is the Fort del Rey, and the signal station. In-coming steamers are signalled at the lighthouse, and afterwards at this station. In the verandah of the English hotel is a key to the various signals, so that one may easily make out what ship is coming, where she hails from, and to what company she belongs. There are two good chemists' shops.

(To be continued.)

SCOTTISH HOSPITALS.

By A. W. WALLACE, M.D.

WE have before us the last reports of the five principal Scottish Hospitals, and of that of Sunderland. Of course annual reports cannot be expected to yield much of interest in respect to the medical and surgical treatment going on in the hospitals, but they afford some interesting and instructive matters in reference to income and expenditure. Of all the reports that of Edinburgh is by far the best arranged. It is of octavo size, extends to forty-three pages, and gives all the financial information in a very compact and accessible form. It does not, like the others, give a list of the names of contributors. We commend the arrangement of the accounts to the study of the treasurers of other hospitals. Similarity in grouping of various expenses allows of comparison between institutions, and that adopted in Edinburgh is undoubtedly the best. There are some things in the Edinburgh Royal which need to be looked into. Its outlay per head is several pounds higher than in any of the other hospitals, and it burns twice as much coal in proportion to its number of beds as do the Glasgow hospitals, leading to an additional expenditure of over £1,300 a year. Moreover, it boasts of having 200 out-patients every day, 60,000 attendances a year. We should like very much to know how many of these could not just as well have been treated by a general practitioner, and have paid a small sum for the advice they got. The words of the report are worth quoting: "Not less than 200 patients have, on an average, attended daily, obtaining the benefit of the high professional skill of the physicians and surgeons, etc., etc." Evidently the medical puff ball is not burst yet.

The outlay on stimulants is not a very heavy item in any of the hospitals. One is curious to know why it should be about 30 per cent. more in the Western Infirmary, Glasgow, than in the Royal. In the Sunderland Infirmary it is less than a fourth of the amount it is in the Western. Another subject of great interest is the cost of surgical dressings. Edinburgh spends no less than £1,163 on antiseptic dressings, in addition to £507 on ordinary ones. Of course if this expenditure is essential to the saving of life one would not grudge it, although it were twice as

much, but if a good deal of it is only a fashion—and like some ladies' fashions, rather an expensive one—we should like to see it relegated to some other place. Mr. Lawson Tait uses the dry method, and his beds only cost about fifteen shillings per annum each. We need hardly say that his results bear comparison with any hospital.

The nursing in all these infirmaries is of a high-class character, especially in Edinburgh. There also great attention is paid to the comfort and well-being of the nurses. They have a diet of varied character, with fresh vegetables and soup, and they are not required to do any menial duties, such as sweeping the wards, cleaning brasses and kettles, and the like. We consider it a profound mistake that in some hospitals ward maids are not employed to do the menial work, and it is put upon probationer nurses. It lowers their position in the eyes of the patients, and so lessens their efficiency. The well-being of the nurses is one which ought to enter into the consideration of infirmary managers far more than it does, especially in respect to diet and hours for recreation. For instance the time of recreation for the nurses in the Glasgow Royal is in the afternoon, which in Scotland means after nightfall for some months of the year, and young girls are allowed to traverse the street by gaslight in one of the worst parts of the city.

Again as to the sources of income. We present a table, which seems to us of great ethical interest. In Edinburgh

	Edinburgh.		Glasgow.	
	£	s. d.	£	s. d.
Collections for all objects in the Voluntary Churches	95,656	0 0	168,443	0 0
Income of the Ministers paid out of these Collections	28,944	0 0	64,427	0 0
Amount paid to the Infirmarys	1,907	0 0	820	0 0
Contributions of all Classes and Denominations to the Infirmarys	5,231	0 0	20,170	0 0
*Contributions per 1000 of population:—				
To "Religious Purposes"	405	6 0	240	12 0
The Infirmarys	22	3 0	28	15 0

*This does not include the endowments of the Established Church nor the voluntary contributions of its members to "religious purposes," but the contribution to the infirmarys includes every class of donor.

two voluntary churches raise nearly a hundred thousand per annum for religious objects. Of this amount they give 30 per cent. to maintain their ministers, and 2 per cent. to provide for the sick poor. The whole contributions of Edinburgh to the infirmary, including those from Established Church, and no church amount to only $5\frac{1}{2}$ per cent. of what the two voluntary churches raise for "religious" objects. In Glasgow matters are much the same. Measured by the money spent on stipends, the good people of these cities seem to fare sumptuously in spiritual things, at least every "Sabbath," while Lazarus gets the crumbs. According to our reading of the New Testament faith works by love and is shewn by good works, and of all others the sick poor are those to whom kindness should be shewn. We believe, however, that in not a few cases "Evil is wrought by want of thought, as well as by want of heart," and that if the claims of the sick poor were more fully and persistently brought before well-to-do people, the response would be greater than it is. It is worth noting that Dublin, with a population of about half that of Glasgow, has no fewer than nineteen hospitals, with beds varying in number from 16 to 200, and providing an aggregate accommodation of 1,400 patients, and supplying a bed to about every 400 of the population. The contributions last year amounted to £14,270, of which about £700 came from working men. The "rebellious and bad city" has some Christian charity in it yet.

does not seem to have much antipyretic power when the temperature is normal, as it was in this case. (3) As I was obliged to discontinue its use in another case, the notes of which I have not now by me, owing to the supervention of very troublesome coryza and extreme coldness of surface after one drachm had been taken in divided doses, no amelioration of suffering having taken place. I consider that this new product is uncertain in its action, and should be administered with great caution, ascertaining the temperature, condition of pupils, and state of heart and pulse, before giving a subsequent dose.

Reviews.

1. *The Medical Annual*, 1888. pp. xvi., 620. 2. *The Dictionary of New Treatment: a Reprint from the Medical Annual*. pp. iv., 432. By a COMMITTEE OF EDITORS. Bristol: Wright & Co. London: Hamilton, Adams and Co.

THESE works are part of an annual effort to help busy practitioners to keep abreast of the times by giving them in handy form a conspectus of the newest theory and practice, and a sketch of the most recent discovery, in each succeeding year. Such knowledge has usually to be obtained by wading through the annual mass of medical literature, and making manuscript notes of whatever is worth remembering; and those who know the trouble of doing this, or the disadvantage of leaving it undone, will not allow the *Medical Annual* to pass among the multitude of ordinary publications, but will welcome it as supplying them with information which hitherto could only be got at with infinite labour; and by the more busy of practitioners could scarcely be acquired at all. The editors in their preface invite help from their readers; and that help can be more efficiently rendered by pointing out defects, than by dwelling at great length on the general excellence of the articles of which the work is composed; so it will not be misunderstood if a considerable portion of the space at our disposal be occupied in bringing out the two weak points which revealed themselves during a somewhat extended examination of the volumes before us. By way of testing the utility of the work on the subject of "New Remedies," to which more than a hundred pages of this year's *Annual* are specially devoted, we set down a few names of drugs, selected at hazard, but on which something new might reasonably be expected, and proceeded to seek for whatever the two volumes had to tell us about them. The drugs chosen were antipyrin, cocaine, saccharin and chian turpentine. Taking up the *Annual* with implicit faith in indexes we turned to the general index, but found no mention of antipyrin. We then turned to the other index in the same volume; but neither was it in its alphabetical place there. It was only on a subsequent occasion that we caught sight of the inch of small print which precedes the index where the words "Antipyretics—See Fever," enabled us to hunt out, on page 13, an entirely satisfactory sketch of the present position of antipyrin in medical esteem. On pursuing the same course with the other volume, we found antipyrin duly catalogued in the index, but when wishing to ascertain its utility in sunstroke, we referred, as directed, to page 356, we found no mention of either the disease or the drug. A further search showed that 356 is a misprint. On another page we found all

that we wanted. With regard to cocaine the search was eminently satisfactory. The information was easily found, and sufficiently copious. And it is observable that whereas the earlier volume adopts the spelling *cucaine*, the later changes it to cocaine which is undoubtedly the more accurate, as derived from *erythroxyton coca*. For *saccharin* we searched all four indexes without finding a trace. On looking for *chian turpentine* we found it, and readily, but it was under the head of "cancer," not of "chian"; and the respectful treatment accorded to the drug is calculated to give Dr. Clay entire satisfaction. After this we gave up trusting to indexes; one result of which was that we discovered on page 88 the missing "saccharin"; and, as in all cases, the article *when found* proved interesting and satisfactory. By way of testing the volumes as to Physiology, Medicine and Surgery we selected at random the subjects *Hydroa*, *Alopecia*, *Brain Surgery*, *Blutplattchen*, *Whitehead's Operation*, and *Aneurysm*. Of all save one we found sufficient notice, and of some—notably of *Blutplattchen*, but under the head of "heart" at page 217 of the reprint—more than could be expected. *Whitehead's* plan of removing the hæmorrhoidal ring seems to deserve mention; but if it occurs we have not found it. Will the editors allow us to point out that in books like the *Medical Annual* facility of reference is of prime importance; and this is best secured by one copious and accurate general index which shall give, in a single alphabetical series, a reference to the page at which every subject, or branch of a subject, may be found. In the *Medical Annual* the articles are themselves in alphabetical sequence, but in two series; and there are two indexes at the end; so that four alphabets have to be searched before one can be sure that one has overlooked nothing. The other, and the only other, weak point in these works is the number of misprints, which though in most cases unimportant, are unusually abundant. Proper names fare somewhat badly. In the reprint we find "*Hebras's* prescription," page 41; and "*Dugardin-Beaumetz*," page 384; and "*John Hopkins*," page 218. At page 124 of the *Annual* there is "*Microsporon Andonini*," so that M. Audouin is in danger of losing whatever immortality his precious fungus may confer upon him. *Urethan*, which is spelt correctly at page 105, appears four times on pages 552, 553 as *urethran*, a word of quite a different suggestion. In the list of brain-tumours at page 140, Dr. Hale White is made to speak of five "*gruma*." Not being acquainted with tumours of that name, we turned to Dr. Hale White's own paper (*Lancet*, 25th September, 1886, page 597,) where five *gummata* are duly chronicled. "Injection" of shell-fish (page 485), is surely meant to be *ingestion*. "*Cerri oxalat*:" at page 11 of the earlier volume is a misprint; and "*Spiritus limonis*," page 14, is not in the P. B. Such trifles as "*Xanthum*," page 428; and "*Porra's operation*," page 432; and "*Teleangiectasis*" may just as well be rectified. At page 505 of the *Annual* begins a kind of *Pharmacopœia* of New Foods or list of medicinal delicacies and pretty preparations wherewith a doctor may often gratify a delicate patient. The "composite concentric pills" designed to act successively on different portions of the intestine, if they can be depended on to dissolve at the right places, must be regarded as a step in the direction of precise medication. The powerful remedy prescribed at the head of page 564, if "exhibited" as ordered on a post card, might save one's books but lose one's friends. We anticipate with pleasure the next *Annual* with a comprehensive index and accurately printed.

R. A. CHUDLEIGH.

Inebriety: its Etiology, Pathology, Treatment, and Jurisprudence. By NORMAN KERR, M.D. London: H. K. Lewis.

AN extract from a page near the end of the book gives the best *resumé* of its contents.

"The gist of the whole matter is that alcohol is an irritant narcotic poison, and that intoxicating drinks have an irritant narcotic poisoning property. The majority of persons are not specially susceptible to this poison, but can go creditably through life, steady, careful, limited drinkers, just as multitudes can live in insanitary conditions without ever appearing the worse for such dangerous surroundings. But there are those who are peculiarly susceptible to alcohol, as there are those who are peculiarly susceptible to sewage poison. Such can be total abstainers from intoxicants, or can drink to intoxication, but drinking in "moderation" is an impossibility to them. Of such material are habitual drunkards made. Apart altogether from moral and religious considerations, they are afflicted with a physical disease, which must be met by physical remedies, the chief of which is unconditional total abstinence from all intoxicants in all circumstances. Even when life itself appears involved, the risk inseparable from the smallest sip of an intoxicating liquor is so great, that the experienced and judicious physician would administer to such an one an intoxicating remedy only with fear and trembling."

The position taken by Dr. Kerr and many other physicians in reference to the nature of inebriety, marks an era in the history of temperance. Hitherto the treatment of inebriety has been empirical, some recommending the "pledge" and moral suasion, others legislative enactments, and others trust in the general advancement of education and enlightenment. Dr. Kerr's book puts the whole subject on a scientific basis, and enables us to appraise the various remedies which have been proposed at their true value, and recognise the different classes of cases to which they are severally adapted. Inebriates may be divided for practical purposes into three classes. 1. The educated, refined, and highly sensitive men and women. The neurotic type of constitution of which Dr. Milner Fothergill speaks so much. In these inebriety is most distinctly a disease. They are conscious of the miserable thralldom in which they are held, but powerless to break the chain. It is of this class that Dr. Kerr's work largely treats, and it affords the most striking examples of alcoholism as a disease closely allied to insanity. The treatment of these cases resolves itself into total abstinence; and, if necessary, residence in a retreat where strong drink cannot be obtained, till the morbid craving for stimulants has passed away. Along with this the use of such remedies—medicinal, but yet more hygienic—as will bring the whole system to the highest possible degree of health. 2. The next class of inebriates is largely drawn from the weak-minded. The long necked, small chinned youth, with retiring forehead, and bird-like profile, known as the masher, gowk, or spalpeen—silly, vain, indolent, with weak will and no conscience, falls an easy prey to the enticements of the drinking saloon. In him inebriety is not so much a disease as a consequence of a mental condition closely allied to idiocy. Often this condition is a temporary one, marking the transition from boyhood to manhood, and if the youth can be safely piloted over the dangerous period, he may develop into a sensible, steady, well-conducted man—not a genius, certainly, but one of the millions of mediocre people, who do their day's work, whatever it may be, sufficiently well to be worth their salt, and for the rest, at all events "do nobody any harm." If a youth falls during this dangerous period, the chances of his restoration are small indeed, and therefore the importance of fencing round this period of life with as many safeguards as possible. Drink, gambling, and fornication are the unholy

trinity which are at present wrecking the lives of thousands of young men just as they are entering life. It behoves all educators, and those interested in the welfare of youth, to consider how young men can be guided through the dangerous period, and most safely launched into the business of life. Idleness and too hard work, monotonous surroundings, want of a happy home life, want of taste for simple and innocent recreations, or inability to obtain them—these are fruitful sources of ruin to young men, and much good will be done by the reversal of these conditions. We believe it will be found that as a rule that irregular habits are much more rare among young men employed in work requiring the exercise of the intellect, such as the draughtsmen in engineering works, than amongst the employees in draper's shops and the like, where there is no higher exercise of mind than is required in measuring cloth or weighing cheese. We have often tried to realise in thought what the life of a grocer's assistant must be—or worse still, an apothecary's assistant in a country town—but we never could get farther than a vague sense of horror akin to nightmare. When this condition of weak-mindedness is permanent, the subjects of it go to swell the class of those "ne'er-do-wells" that form the skeleton-in-the-house in so many respectable families. The only way that we can see for disposing of these unhappy persons is to infringe the "liberty of the subject" so far as to gather them together in some district far away from public houses; group them in families of a dozen each, and employ them in agriculture. 3. The great mass of habitual drunkards is drawn from the working and artisan class of society. Their drunkenness is neither allied to insanity nor the result of weak-mindedness, but is part and parcel of that low moral condition which makes them take pleasure in cock fighting, prize fighting, and all those debasing pursuits which go to make up the life of the depraved. They drink because it adds to the zest of these pleasures. They drink because it makes them forget their care and labour. Women especially drink because they can for a little forget the worry of their household; and then before long they drink because the drink fiend has got the mastery of them, and they cannot cease to drink even if they would. Such is the condition of millions of the population in the great cities and in the manufacturing and mining districts of these kingdoms. They have been called the lapsed masses, but in our view they are rather the un-raised masses of the commonwealth. They are the uncivilized residuum which has come down from past generations. What the remedy is for this state of things may best be learnt from the study of the history of the past. The writer is old enough to recollect when it was in no wise remarkable for people in the middle class of respectable society to be "elevated." It was just the close of that period when Lords of Session in Edinburgh were famous for being able to see every gentleman of the long robe who dined with them under the table; when it was told of a nobleman that he had his decanters made round on the bottom, so that they had always to be passed from hand to hand; when Hogg could write of the author of *Waverley*, in his young days, that "drunk or sober he was aye the gentleman." The writer well recollects hearing a banker describe how, in his earlier life, when he gave a dinner party, every one went home with "a bottle of port under his belt." All this is changed now, and fifty years have sufficed to bring about the result. Christian effort, temperance effort, the spread of knowledge, and a general change of habits, have all contributed to the reformation. There must be work of

the same kind among the lower stratum of society. Among physical improvements none will be of greater benefit than the better housing of the working classes. Dr. J. B. Russell, Medical Officer of Health for Glasgow, has said, with no less truth than force, "Consider whether, since the world began, man or angel had ever such a task set before them as this—the creation of the elements of a home, and the conduct of family life within four bare walls." Yet this problem has to be solved in forty thousand single rooms in Glasgow. Is it any wonder that men and women in such circumstances drink in the very madness of despair. Let better houses be put within the reach of the poor, and an immense impetus will be given to the work of those devoted men and women who are "on the night shift," as one has called it, labouring to rescue their fallen brothers and sisters. It will be possible then for the rescued to lead decent wholesome lives.

These are some of the reflections which have been suggested by the persusal of Dr. Kerr's work. It is a book to study for oneself, and we think that every medical man who desires to fulfil his duty faithfully to his patients, will possess himself of it. The time has gone by when a case of inebriety can be passed over with the remark that "the poor fellow is no man's enemy but his own." To neglect such a case has become as criminal as to neglect a case of enteric fever or pneumonia.

A. W. WALLACE, M.D.

Vaccination Vindicated. By JOHN C. McVAIL, M.D., D.P.H. Camb. London: Cassell & Co., 1887.

THIS volume, of 176 pages, professes to be, and is, "an answer to the leading anti-vaccinators." It was begun merely as a reply to Dr. Alfred Russel Wallace's monograph on the subject, and has developed into a full and complete commentary on much of the anti-vaccination literature of the day. The author has performed the self-imposed and irksome task of reading all such writings, and has been struck by the very narrow compass within which the whole argument against vaccination is carried out. Few medical men have time to undertake the labour of rebutting the various misrepresentations of which vaccination is the object. There are some things which are so well grounded as to rank with axioms, and do not need constant criticism. The history of vaccination gives it a claim to rank with those axioms which may be taken on trust, and on which the mind need not be left open for further evidence and enquiry. The author has constructed a work which may form a handy reference book to those who are unprepared to refute every assertion that may be made. He believes it to be "the duty of those who know the value of vaccination, who understand the danger against which it protects, and who are satisfied of the all but complete harmlessness of the operation," to teach "the truth about vaccination, the truth as demonstrated to Parliament, the truth as learned by ever growing experience of men who give their lives to learning it, the truth about a duty which cannot be neglected except at the price of indefinite suffering and loss of life." He pleads for "instruction of the people in the matter of vaccination, instruction by the teachings of history, if that will suffice, otherwise by the removal of obstacles to direct experiment, which may convince the sceptical, if they are able to be convinced; but surely not, if our best endeavours can prevent it, by leaving helpless children to die by thousands from small-pox, as assuredly they will die if a large unvaccinated community of them be permitted to grow up in our midst."

R. S. S.

Short Notices.

Notes on Dental Surgery. By J. SMITH, M.D., LL.D., F.R.C.S.E. Edinburgh: Maclachlan & Stewart.

THIS is a little book of seven chapters, giving in seventy-six pages "a compilation of memoranda" on the anatomy, physiology, pathology, and treatment of the dental apparatus. His idea that caries "may be and is originally a vital action set up in the dental tissues"—"a true pathological lesion"—is incompatible with the more modern views as to its nature. The chapters on extraction, on filling, and on anæsthetics, leave little to be desired. As regards the production of anæsthesia, we hold that this should always be the work of some other person than the operator, and that inasmuch as the production of absolute insensibility must always of necessity imply some little risk to the organism, the anæsthetic should always be in the hands not of the youngest and most inexperienced medical man, but of one who is thoroughly familiar with its properties and uses.

R. S. S.

Outlines of Qualitative Analysis. By GEO. W. SLATTER, A.R.C.Sc., F.I.C., &c. London: Thomas Murby.

THE number of books on this subject is increasing rapidly; the supply must already be in excess of the demand. While this reflection will give small comfort to authors and publishers, a little is afforded to the general body of students, as there appears some likelihood of the best books surviving and being of use. It is in the latter class that we unhesitatingly place Mr. Slatter's book. His long experience as a teacher at the Salt Schools, Shipley, enables him to give the various tests and reactions in a manner which will be of decided use to young students. Directions are given for preparing the reagents to be used in the laboratory, and also for finding all the bases and acids which are usually included in a course of qualitative analysis. In the 140 pp. we are unable to find a useless paragraph.

W. ACKROYD, F.C.S.

On Infant Feeding and Infant Foods. By JAMES McNAUGHT, M.D. Small 8vo., pp. 72. Manchester: John Heywood, 1888.

THIS is a little book containing a very large amount of valuable information upon the subject of which it treats. The fatal consequences of improper feeding are herein clearly set out, while the facility of averting these evils is shown to be derived from the knowledge of the ordinary facts connected with the process of digestion. Judicious directions as to the feeding of infants are given, and enforced by a concise summary of the physiology of digestion. The rules by which artificial feeding is to be guided are fully expounded, and illustrated by a description of the substances which may safely be employed for that purpose. We cannot doubt but that this little treatise will prove of the greatest value to young mothers and to nurses. We could have wished to have met with a protest against the use of long India-rubber tubes with the feeding bottle. An American writer forcibly—but not too forcibly—expressed his opinion of these by the remark that Herod would have rejoiced had he only known the use he could have put them to, had they been known in his day.

W. B. KESTEVEN M.D.

The Provincial Medical Journal,

MAY, 1888.

WHILE medicine is advancing entirely on new lines, opening out new fields undreamt of by our ancestors, it, at the same time, shows a tendency to revert to some of the methods so much in repute amongst the earlier practitioners of our art. HERODICUS, surnamed the Gymnastic, and said to have been an instructor of HIPPOCRATES, was one of the earliest of the regular physicians to recognise the advantages of bodily exercise, not only in the treatment of disease, but in the preservation of health, and he was followed by the great master, HIPPOCRATES, who, in his turn, was also followed by the minor lights of ancient medicine. The modern system of massage finds its counterpart in the process of friction or inunction, indulged in by the Greeks and Romans, who recognising the great advantage of baths, also added to them friction. In the Turkish bath, under the name of champooing, massage has been long practised, and what is now a modern fashionable custom, is in reality only a revival. Massage in gynæcology naturally follows in the current, and is but a special application of general principles, and is part of the revival. Professor VULLIET, Geneva, in the *Journal de Médecine de Paris*, 8th April, has a long article on the value of massage in gynæcology, so that it is evident the method is receiving the attention of regular practitioners, and is being rescued from the hands of empirics. Professor VULLIET tells us that THURE BRAND, who is not a medical man, deserves the credit of introducing this method, for the absorption of old pelvic exudations and to connect uterine deviations, and that, though BRAND's manipulations were characterised as indecent and brutal, yet the method possesses a real efficacy. SCHULTZE intrusted some patients to Dr. PROFANTER, who was one of BRAND's disciples, and satisfied himself so far on the efficacy of the manipulations, as to guarantee the authenticity and faithfulness of the plates with which PROFANTER has illustrated his work, "Die Massage in der Gynækologie," Wein, 1887. Professor VULLIET, about two years ago, took up the study with some doubt, and now is able to state that, after having gone through an apprenticeship, he has succeeded in curing, by massage, many of those patients who go from one specialist to another, and whom he had vainly treated by other methods. The gynæcological masseur, according to M. VULLIET, must be acquainted with massage in general, must be a good diagnostician, must have a fine tactile sense, and must have patience and perseverance. The manipulations must be made with both hands externally, or with one in the vagina and the other external. Special attention must be paid to the state of the nails, gentleness, firmness, and evenness of touch, are evidently required; the mottoe should be "*festina lente*." The chief indications for uterine massage are infiltrations, rigidity, mal-positions of the uterine surfaces, or adjacent parts, and these have to be brought into a state of suppleness, or corrected by gentle

stroking, pressure stimulation, both hands acting in some cases externally, or sometimes one hand in the vagina, and the other on the abdominal walls. We need not wonder that BRAND was accused of practising a method so liable to abuse as the one described by M. VULLIET. It is well known that in a certain class of cases the speculum became a source of pleasure, the continued use of it brought on a habit; so that the speculum, useful and admirable under certain circumstances, became a reproach to obstetrics and gynæcology. The new system, in the hands of the empiric, may be used for most improper purposes, and is certainly one, as Professor VULLIET insists, only to be used or employed with due precautions against excitement. The wave of fashion is now sufficiently directed to general massage, and we have had revelations that even the general application of it has been very much abused, so that a caution is needed against the more special application which Professor VULLIET so strongly advocates.

ANTIPYRIN, though a patent medicine in every sense of the word, has been taken up in nearly every country; it has been used both scientifically and empirically. It has had the good fortune to have been introduced to the profession by presumably men of good position, and in the profession, as in society, an introduction has its value. The new chemical has not, perhaps, had the popularity of cocaine, but its literature approaches it very closely in magnitude. Cocaine has been relegated into its proper sphere of usefulness, and is now a standard preparation. Antipyrin will have to go through the necessary sifting process, and will in due time have also its proper rôle. Meantime, it may not be without profit to look at some of the uses to which it has been put. Dr. THOR, of Bucharest, has found antipyrin an excellent substitute for bromide of potassium in nocturnal emissions; it is preferable, as it does not produce acne. He prescribes from seven to fifteen grains just before going to bed. He prefers the tablet form. Also in cases of the so-called sexual neurasthenia of BEARD, the same drug has proved very useful, but it requires larger doses. Dr. THOR commences with sixteen grains a day, and gradually increases to about thirty grains. It is used in this condition as an anti-spasmodic, under which heading it has been employed by GERMAIN SEE, who, moreover, claimed for it a place filled by morphine. It has been employed to relieve the pain of colic, gout, rheumatism, toothache, and we publish this month a communication in which its use for migraine has been pointed out, thus bearing out the observations, already made in France and America, with the drug for the same affection. We need not wonder that it should have been tried in whooping-cough and sea-sickness, and that it should have been praised in both complaints. Chorea, epilepsy, mania, asthma, dysmenorrhœa, hay fever, etc., have also been treated by it with satisfactory results. We thus see that it is going through the process of being written about, and that it is still in the experimental stage. When first

introduced, studied by DEMME and FILEHNE, its antipyretic properties were those which were chiefly observed. Subsequent investigations have confirmed the accuracy of these observations, and it soon displaced antifebrine. Antipyrin is not without its dangers. Symptoms of poisoning have occurred after its use, and it brings on vomiting, nausea, extreme and alarming prolapse. Some patients, owing to some idiosyncrasy, are peculiarly susceptible to the influence of antipyrin, and, unfortunately, we cannot estimate this until they have taken the drug; so that those who use the medicine should bear this fact in mind, and be prepared for any symptoms which may arise in the form of catarrh, gastric pains, urticaria, and great depression in temperature. It may be possible that in many cases of poisoning reported, the best antipyrin had not been used, though we believe that usually the patented article has only been employed. KNORR's antipyrin is sold in little tins, so that it is possible to know the source of the specimens used. KNORR is, we believe, a medical man, and as he found out this new body whilst experimenting with quinine, he considered it justifiable to reap a trade advantage from it. According to some of our French exchanges, we learn that the French physicians do not consider themselves bound to respect Dr. KNORR's patent, as it is against French laws to have a copyright in medicines; so that manufacturers in France will be able to make antipyrin, and sell it to French physicians.

THE new Local Government Bill is imperfect in leaving the Sanitary Service in almost its present piecemeal condition, and we might almost say it is retrograde. We want some such system or project as that suggested by Dr. HENROT, Professor at the School of Medicine, and *Maire* of Reims. It may be useful at the present time to bring the scheme under the notice of our legislators, and we publish a translation of it, a modification of which might be applied to our own conditions. Dr. HENROT's scheme is embraced under the following heads:

SANITARY LEGISLATION.

I.—Revision and completion of laws, decrees, and rules, concerning sanitary legislation—viz., to enforce laws against epizootics, etc.; to modify existing laws; to compel (a) declaration, (b) isolation, and (c) disinfection:

- (a) A declaration of the names of persons suffering from infectious or contagious disease shall be made to the *Maire*, within twenty-four hours, by the head of the family, or the senior member thereof, or in default by the proprietor or housekeeper, or in default by the medical attendant.
- (b) Isolation of persons suffering from contagious disease, disinfection of apartments, objects of clothing and bedding, shall be obligatory.
- (c) Persons suffering from contagious disease, small-pox, scarlatina, etc., shall not expose themselves on highways, attend school, etc.; penalty from 16 to 300 francs, or imprisonment from six days to six months for violation thereof.

Unhealthy dwellings to be attended to, vaccination or re-vaccination to be obligatory, creation of houses of isolation, to be embraced in this plan.

II.—The first service to be Communal, under the *Maire*, and at the cost of Commune, and to be constituted as follows:

- (a) Communal Council, (b) Bureau of Hygiene, (c) Communal Medical Sanitarian.
- (a) This to consist of (1) Council of Surveillance, (2) a Commission on Unhealthy Dwellings.
 - (1) The Commission of Surveillance to be presided over by the *Maire*, to carry out the application of measures of hygiene, and to consist of from ten to twenty members—doctors, chemists, engineers, veterinarians, pharmacists, *industriels*, to meet annually, or as often as necessary, to draw up bi-annual reports.
 - (2) The Commission to look after dwellings, and report bi-annually.
- (b) A Bureau of Hygiene to be established, presided over by a Doctor in Medicine, to be nominated by the *Maire*, to direct service as to prophylaxis, statistics, to send each day to departmental bureau a sanitary bulletin, and publish an annual report. To have under his orders (1) the chief of the bureau; (2) the sanitary medical officers charged with registration of deaths, inspection of schools, and the sanitary surveillance of the different districts; (3) the veterinary inspector, and the inspector of *abattoirs* and eatables; (4) the inspectors of dwellings, establishments, water-closets, etc.; (5) the surveillance of infants, and children in manufactories; (6) the employés in the work of disinfection; (7) the archives; (8) plans, apparatus of all kinds, the laboratory of chemistry, microscopy, bacteriology; (9) the application of the law of declaration, isolation, and disinfection; (10) the homes of isolation, lodgings, etc.
- (c) A Communal sanitary physician to be provided for the *petite Commune* to discharge similar duties.

III.—A Departmental Bureau to be established under the Prefect, and to be carried on at the cost of the department, to consist of:—

- (a) A Departmental Council of Hygiene, to be presided over by the Prefect, made up of the hygienists of all the departments, with twenty or thirty members, as doctors in medicine, professors of hygiene, engineers, pharmacists, veterinarians, or *industriels*, to meet twice a year, or as often as the Prefect deems necessary, to publish an annual report, and have surveillance of the Bureau of Departmental Hygiene.
- (b) A departmental sanitary physician, a diplomate of public health, to be appointed, who shall have the following powers: (1) He shall be chief of the bureau, and be nominated by the Minister of the Interior, on the recommendation of the National Council of Hygiene; (2) shall be medical adviser in case of epidemics in the department; (3) vice-president of the Council of Hygiene (presidency reserved for the Prefect); (4) Director General of Public Health in the Department; (5) Inspector General of Sanitary Medical Officers and of the Directors of the Communal Bureau of Hygiene; (6) Inspector General of Dwellings, insalubrious or dangerous; (7) Inspector of Human or Animal Vaccine; (8) Inspector General of Infants, Children, and Minors employed in Manufactures; (9) Inspector of Public Establishments, as Lyceums, Hospitals, Asylums; (10) Inspector of Public Works, as Water Supply, Sewerage, etc.; (11) Inspector of the Bureaux of Statistics and Demography.

Obligations.—(a) To receive the daily sanitary bulletins sent by the Communal sanitary officers; (b) to send every fifteen days a report of the sanitary state of the Department to the Minister of the Interior; and (c) to prepare an annual report for the Council of Departmental Hygiene.

- (c) A Bureau of Departmental Hygiene to be established with a chief and laboratory under the Council of Departmental Hygiene. The organisation to consist of a number of employés proportionate to the importance of the department, with library, archives, and with material, apparatus, plans, etc. The laboratory to be fitted up for chemical and bacteriological research.

IV.—A National Council to be established under the surveillance of the Minister of the Interior, and to be carried on at the expense of the State. This Council to be made up as follows: (a) By the Academy of Medicine, which shall constitute the Grand Council of Public Health, and make an annual report of sanitary matters in France. (b) The sanitary general administration shall be under a *chef de division*, who shall be a medical man. There shall be then two sub-divisions: (i.) public assistance; (ii.) public hygiene.

(i.) The first shall consist of a National Council of Public Assistance, of fifty members, nominated by and presided over by the minister, two senators, two deputies, two members of the Academy of Medicine, two members of the Institute, two members of the Faculty of Medicine, other medical men in the civil and military hospitals, engineers, etc.; and this Council shall report annually. There shall be a Medical Director General, who shall control and direct and carry out the necessary sanitary inspection and surveillance.

(ii.) The National Council of Public Hygiene shall also consist of fifty members as above, and shall have also a Medical Director General.

(iii.) There shall be a Central Bureau, comprising (1) a department exterior and international, to look after congresses and international exhibitions, exotic diseases, quarantine, lazarettes; (2) a service of statistics and demography; (3) a service of the Interior, which shall regulate all matters relating to the health of towns, water supply, public health works, schools, prisons, etc.; labour of adults and children, vaccination, foods, drinks, and, in fact, everything that falls within the province of our English Local Government Board.

This scheme of Dr. HENROT is elaborate, but it has a unity, and is well worthy of consideration. We could easily apply the principles underlying his plan to our English conditions: (1) Beginning with the Commune, the parish or town, we should have the Poor-law medical officers, medical officers of health. They are already appointed over areas, and they best know where disease exists, or where it starts into existence. The Poor-law medical officers did the work of sanitation in England before STANSFIELD'S Act was introduced. The value of their work may be seen by consulting CHADWICK'S report on the "Labouring Classes." They would have to report daily or weekly to a county authority. (2) There should be a County Supervising Medical Officer, who would have as his sub-officers the local medical officers of districts, and who would perform all duties incidental to such a position, and who would report to the Central Bureau, the Local Government Board, London. (3) The Local Government would have its principal medical officer, staff of consultant medical officers, who would be in touch with the whole country by the local medical officers. We should thus have a unified system, and one worthy of a country which spends millions a year on sanitary work.

WE published in the April number the full text of the new Warrant, establishing a Volunteer Army Medical Reserve. Those who have followed the history of the volunteer movement, so far as medical men are concerned, will recognise in this Warrant a first instalment towards the building up of a medical service which shall serve the country in any great national emergency. The Warrant does not give us all we require, but it is the

thin end of the wedge, and we may reasonably hope that further concessions will be made, which will satisfy not only the volunteer medical officers, but the Army Medical Department. The Militia Medical Staff has now virtually ceased to exist. It was only to be expected that an attempt would be made to supply its place. The volunteer medical department has, by the exertions of a few active men, risen from a position of comparative uselessness into one of even great national importance. In the early days of the volunteer movement surgeons were attached to corps, to which they could only be considered as ornamental appendages. They wore uniform, appeared on parade, attended regimental dinners, but they had nothing to do; they had no medical transport, bearers, or stretchers; they had no system of drill, no organisation. Even so lately as the Windsor Review, few regiments at that great assemblage possessed means of dealing with the sick members of their corps. The nucleus of a medical corps was then formed, and Lieutenant MACLURE had a small staff of bearers and ambulance waggons, and it was seen then what great possibilities lay in the development of the movement which he initiated. Since that time events have moved on rapidly. The War Office has recognised the Volunteer Medical Department. It has granted to each regiment two bearers per company. It has formulated a scheme of drilling and examination, granted certificates, and the right to wear the red-cross badge to those who have passed a qualifying examination. Still more, it has assisted in the formation of a Volunteer Medical Corps, having an autonomy of its own, and leaving the regimental system untouched. All this has been accomplished by the activity of volunteer surgeons, but their activity would not have been of much use had they not been assisted by the medical officers of the regular army. Army medical men have thrown themselves into the new movement, have given lectures, carried on classes, and in every way favoured the new departure. Surgeon-Majors EVATT, SHEPHERD, and others, must have clearly seen what would be the ultimate end of this movement, so that army medical men need not be surprised that Government have endeavoured to bring into use the material created. The militia surgeons have had the charge of troop and stationary hospitals, and depôts. In some cases civilians had charge of troops. In view of the gradual extinction of the militia medical officers, the Government desired to find substitutes in the volunteer medical officers who had educated themselves in army medical work, and who had obtained certificates of proficiency, so that, as we have said, the Warrant is purely the result of what has been done by the army medical officers themselves, at the initiative of the Volunteer Medical Service. The English Army is built up on the selective principle: we take whatever we find best in other army systems, and graft them on our own, whether in the shape of clothing, weapons, or drill; and the Army Reserve scheme appears to us to have been copied from the German system, where behind the regular army medical staff, they have a strong reserve in case of

any grave national emergency. The conditions of service under the new Warrant are much the same as those by which volunteer medical officers are now bound. Surgeons attached to volunteer regiments would have, in any grave emergency, to go with their corps to any place ordered, and no more is expected under the new Warrant. We consider that the new scheme should be accepted, trusting that it will be subsequently modified and improved.

Annotations.

"Forsan et hæc olim meminisse juvabit."

SEWING MACHINES.

THE sewing machine has been blamed for producing affections of the uterus, and there is very strong evidence brought forward to substantiate the charge. The position of the operators, the height of the seat and the nature of the chair, the condition of the machine, have a great deal to do with the ill-effects resulting from long-continued use of these useful machines. Dr. Bates, of Alliance, Ohio, tells us that women might save themselves a great deal of suffering by attending better to the lubrication and cleaning of the mechanism. If a machine is clogged up with thread, etc., or is rusty and dirty, it will not work easily, and will require a considerable amount of constant propelling power. We believe that Dr. Bates' advice is sound, and that a clean, easy running machine, requiring only a slight degree of force on the treadles, will not be injurious. There is another point of importance—viz., that tight corsets should not be worn, especially if the operator has to bend over the machine.

THE SALE OF PATENT MEDICINES.

WE learn from the *Medical Record*, New York, that a Bill for prohibiting the sale of patent or secret medicines has been introduced into the Assembly of the State of New York, by Mr. J. W. Smith. It provides that no person or firm shall sell any medicinal preparation without filing the formula of the preparation with the State Board of Health, and receiving a license or certificate from that body. It further provides that no so-called secret or proprietary medicine shall be sold, unless there is a printed formula showing the nature of the compound on the bottle, and also the words, "Sale authorized by New York State Board of Health." In view of the revelations about a secret remedy published in a late number of the *New York Medical Journal*, it was time that some such regulations were passed.

THE CASE OF DR. MARSHALL.

A MEETING of medical men was held at the Croydon General Hospital on March 28th to hear a statement from Dr. E. Marshall, on his dispute with the Holborn Board of Guardians. Dr. Marshall has been medical officer of the Holborn Union for thirty-two years, and he has been threatened with dismissal for an alleged neglect of duty in not giving sufficient time to his patients. The meeting

was largely attended, with Dr. Alfred Carpenter in the chair, and after hearing Dr. Marshall's statements, the following resolutions were unanimously passed:—1. Moved by Dr. Coles, and seconded by Dr. Hearnden: "That having heard the statement made by Mr. Edward Marshall, and the correspondence which has passed between him and the Holborn Board of Guardians, this meeting is of opinion that the action of the Holborn Board is unjust to an old and well-tried officer; that the circumstances in no way warrant the action which that Board proposes to take; and that the President of the Local Government Board be requested to refuse his consent to the proposed removal of Mr. Marshall from his office." 2. Moved by Dr. Parsons, seconded by Dr. Wilton: "That it is only a matter of justice to the medical profession that medical and sanitary officers who have fulfilled their duty to the satisfaction of a local authority should be entitled to some superannuation according to their length of service, and the duties performed." 3. Moved by Mr. A. Kelsey, and seconded by Mr. Moger: "That this meeting is of opinion that no sanitary or medical officer holding office under any public authority should be removable except for grave neglect, or for some other cause which has rendered him incompetent to perform the duties of his office." This meeting was most creditable to the practitioners of Croydon, and we trust that Dr. Marshall will have the whole support of the Poor-Law Medical Officers' Association.

THE PREVENTION OF HYDROPHOBIA IN FRANCE.

THE key-note we struck on the Pasteur treatment was contained in the following paragraph: "Something more is required than even a remedy for hydrophobia. Even though Pasteur gave us a remedy against the bites of rabid dogs, yet we have something more to do: we have to extinguish the disease in the dog" (p. 49 "M. Pasteur and His Methods," 1886). The English Hydrophobia Commission in their conclusions repeated this; the Committee of the House of Lords re-echoed it, and now the French Academy have taken up the note. The following resolutions were adopted at a recent sitting of the Academy: "Considering that the number of cases of canine rabies are increasing in the Department of the Seine, and even in France, the Academy requires the urgent adoption of the following measures: (a) Utilisation of the police, or the creation of a special staff to look after dogs; (b) obligatory wearing by dogs of a badge showing that dog tax has been paid; (c) vigorous application of articles 53 and 54 of the decree of 22nd June—viz., (1) the administrative authority may order that all dogs shall be muzzled or led by a string; (2) when a case of rabies has appeared in a commune, the mayor may issue an order that for six weeks at least dogs should be led by a string." These conclusions conclusively justify our position. The following report had been received from Holland: "The Government has had knowledge of twenty-three cases of persons bitten by animals rabid, or suspected of rabies, twelve of whom underwent at Paris the anti-rabic treatment

of Pasteur, out of which number one died—namely, a boy aged thirteen, bitten by a rabid cat, on June 13th, 1886, who underwent twelve inoculations. The eleven remained at home, and have remained perfectly well. These results are absolutely unfavourable to the method, since the only death registered from rabies during 1886 belonged to the series treated at the Institute.” The death-rate in France continues at a high rate. The number of patients from foreign countries have notably diminished, though the number of dog-bitten persons is not on the decrease. The increase in France is admitted by the French Academy. Nine deaths took place in 1887 in the Department of the Seine, the average being five for a period of thirty years. M. Pasteur’s inoculations have been tried in every conceivable form. Discredited in America, Germany, Austria, and Portugal, condemned in Holland, and we believe in Belgium, damned with faint praise by the English Commission, M. Pasteur’s disciples still strive to keep the system alive, but it appears to us the method has received a severe check from the recent utterances of the Academy of Medicine. When patients died after the treatment, it was alleged that they came too late—three days or a week after the bite. This excuse can hardly apply to Alphonse Marinot, who commenced the treatment *one hour* after being bitten. A soldier of the 29th Foot Regiment, he was bitten on February 17th, 1888, by a dog suspected of rabies, which he was anxious to kill. He was immediately conducted to the Institute Pasteur, and followed the treatment with the greatest regularity up to March 16th, when he was discharged “cured” by M. Grancher. On the 29th of March Marinot was seized with pains at the seat of the bite, dying on the 1st of April at Val de Grace, with all the symptoms of rabies. Two other patients have died recently.

FREE TRADE IN SURGICAL INSTRUMENTS IN AMERICA.

THE State Medical Society of Georgia has drawn up a petition, to be presented to Congress, urging the repeal of the tax on surgical instruments, appliances, etc. The reasons for the change will be at once agreed in by free-traders, and by foreign manufacturers, but we fear that there is not much probability of this petition being accepted. Those who have axes to grind in America will strenuously oppose the introduction of foreign-made articles free of duty. The American public must be content to pay an increased price, even for inferior articles, to keep up monopolies.

THE DEGREE OF M.D. FOR PRACTITIONERS.

WAITING for the establishment of the new University in London, students will have to content themselves for some years to come with licenses from the College of Surgeons and College of Physicians. This is hardly fair upon them, and we wish we could see some way out of the difficulty. It is clear that the M.D. is now a desideratum. There is a very important letter in the *British Medical Journal*, April 14th, which states that a petition is to be presented to the Senate of the St. Andrew’s University, praying that

all medical men of ten years’ standing may be eligible for the practitioner examination for the M.D. degree, without restriction as to age or residence. The Senate would not oppose such a scheme; if it were well supported by a large number of names. Already one petition to this effect has been lodged, containing the names of representatives of nearly every British University, who, whilst not desiring a change for themselves, support it as a means of justice to others. The letter is signed by Mr. B. Jones, Leigh, Lancashire, who will receive the names of all those who are in favour of the change.

SHOULD MEDICAL MEN TAKE OUT PATENTS?

THIS question is at present exercising the medical mind. It has been the custom for medical men not to patent instruments, appliances, etc., but now this rule is frequently broken. Medical men have always secured a copyright for their books, and some of these copyrights have been valuable. Custom has sanctioned this practice, and it is to custom we must appeal. It is for the profession to make its own rules; it does not follow because copyright has been sanctioned by the profession, that therefore it is justifiable to secure a patent for an instrument. Analogy does not here hold good. The best traditions of medicine are certainly associated with the non-patenting of anything that can be useful to mankind. Our predecessors have given us some of the very best instruments and appliances, free from any restrictions, and they threw their talent and inventions into a common fund, upon which all can draw. The custom of the profession is now, not to patent instruments.

THE HORSE TAX.

THE hostility to the new horse tax has fortunately resulted in a decision, that medical men who use their horses for professional purposes and not for pleasure, shall not be liable to the tax. The number of petitions against this obnoxious duty has evidently had a good effect.

SUPERSTITIONS ON THE HOHENZOLLERN FAMILY.

THE physicians of the Emperor would be able to form a prognosis as to the result of the Emperor’s illness if the following legend were true: It is said that before the death of any of the Hohenzollerns a white lady appears. More or less apparently well authenticated cases of the apparition of the white lady at Berlin have occurred in 1840 before the death of Frederick William III., and in 1861, previous to the death of Frederick William IV. We fear that the days of the Emperor are numbered, in spite of the skill of his attendants. There is just as much reason to believe in these superstitions, and as much groundwork for investigation, as in the recent elaborate inquiry into the researches of M. Luys, instituted by the French Academy. If little bottles of medicine, filled with such fluids as morphia and prussic acid, can influence a patient at a distance, as claimed by certain scientists, then certainly there is no reason why disembodied spirits should not revisit the earth. It all depends on the IF.

New Remedies.

THE chemistry of *Strophanthus seeds* is still under discussion. The statement by M. Adrian that the glucoside strophanthin splits up into an alkaloid and glucose has been objected to as inadmissible, since strophanthin contains no nitrogen. M. Catillon affirms that these seeds contain another glucoside, which is nitrogenous, and which yields an alkaloid when treated with acids. He finds that when the seeds that have been exhausted by alcohol and ether are treated with boiling acidulated water, they give up a considerable quantity of a glucoside, associated with a well-marked alkaloid, which latter has, however, only been obtained as yet in the amorphous state. The varieties of seeds which are now being sent to Europe appear to differ considerably from each other. One of these, which M. Catillon refers to—*Strophanthus glaber*—is found to contain about 5% of a strophanthin, which differs from that yielded by *Strophanthus Kombe* in its crystalline form, which is that of four-sided lamellæ, the sides measuring one to two millimetres, whereas that of *Strophanthus Kombe* is in acicular crystals. It also is not precipitated by tannin, and is not coloured in the cold by sulphuric acid, but when heat is applied it exhibits a red colour, passing to green. If a little solution of perchloride of iron be added, and heat applied, the green colour is produced immediately. In this respect it differs from digitalin, which under the same condition gives a blue colour with hydrochloric acid, and when heated, it affords a yellowish green colour. The strophanthin of *Strophanthus glaber* is non-nitrogenous and toxic.

Several reports have recently been issued concerning the anæsthetic action of *Erythrophlaine*, of which one of the most important is that of Professor Kaposi, of Vienna, who has used it sub-cutaneously in seventeen cases. In doses of two and a half to ten or twenty milligrammes it produced, after about fifteen minutes, local anæsthesia, which lasted from one to three hours; this was restricted to a small central zone of the injection area, the larger marginal zone being paræsthetic. Local symptoms of irritation and smarting were produced by even the smallest doses, and sometimes lasted for one or two days. Doses of twenty milligrammes caused general symptoms of poisoning, after periods varying from fifteen minutes to an hour, evidenced by dilation of the pupil, dizziness, weakening and slowing of the action of the heart and pulse, quickening and shortening of the respiration, nausea and vomiting, the symptoms continuing for several hours. It is obvious, therefore, that this powerful alkaloid does not present any advantages as an anæsthetic, especially having regard to the smallness of the dose, which produces poisonous symptoms.

Some light has been thrown on the uncertain action of *Cocaine* by the investigations of Dr. B. H. Paul, who has shown (*Pharmaceutical Journal*, p. 781) that the alkaloid is now chiefly prepared from crude alkaloid imported from Peru, and that it is likely to vary in quality according to the price paid for it, it being impossible to prepare it in a perfectly pure state at the low price at which it is sometimes sold. He has, however, placed in the hands of all who desire to obtain the pure drug a ready means of ascertaining its freedom from impurities. He states that when a few drops of ammonia are added to a solution of cocaine hydrochlorate, the alkaloid should be precipitated in a crystalline condition, leaving the supernatant liquid quite clear; whereas, if amorphous alkaloid be present, the supernatant liquid remains milky for some hours. Another test consists in evaporating a solution of the suspected hydrochlorate of cocaine. If the amorphous alkaloid be present, the solution becomes acid to test paper. The solution of the pure hydrochlorate may be evaporated to dryness without the slightest trace of acidity being developed. The difficulty in preparing the hydrochlorate of cocaine in a pure state is due to the fact that the same re-agents precipitate the amorphous alkaloid at the same time. The pure alkaloid cocaine can, however, be much more easily purified than the salt, inasmuch as it is very sparingly soluble in water or dilute alcohol, while the amorphous alkaloid is more soluble; hence, on adding water to a solution of the crude alkaloid in strong

alcohol, the pure crystalline alkaloid is precipitated, and the amorphous alkaloid left behind. Under these circumstances, if due care be taken pure cocaine is easily obtained. Dr. Paul has, however, pointed out that if cocaine be left in contact with ammonia, or even if it be heated with alcohol or water, it is liable to be split up into benzoyl-ecgonine. The hydrochlorate is, however, much more stable, and if pure, undergoes no alteration when its solution is evaporated to dryness.

Calycanthus glaucus, popularly known as Carolina allspice, the bark of which is said to be highly esteemed in Virginia as a domestic remedy for intermittent and malarial fever, has recently been found to contain 2% of an alkaloid in its seeds. Although the physiological action of the alkaloid has not yet been investigated, it seems highly probable that it may possess some medicinal activity, since its discovery was led up to by the supposed poisoning of cattle from eating the seeds of the shrubs.

The discovery that oil of tansy (*Tanacetum vulgare*) produces symptoms closely resembling those of hydrophobia has been followed up by M. Peyraud, and the further discovery has been made that a subcutaneous injection of the oil is sufficient to prevent the action of the virus of hydrophobia when administered subsequently. In his experiments, four rabbits were treated with oil of tansy, and then inoculated with the virus of rabies, but no symptoms of hydrophobia were manifested even nine months after inoculation, although two other rabbits, which had not previously been subjected to the action of the oil of tansy, were killed by the same virus that was used in the first experiment. The value of the oil of tansy as an antidote instead of preventive, does not appear to have yet been determined.

Another new antipyretic has been added to the already long list of these compounds by Professor Demme. It is named *methyl-tri-hydroxychinoline-carbonic-acid*, and has the formula $C_{10}H_{10}(CH_3)NO_3$. The similarity in constitution of this body to thallin led to experiments being made with it. The compound was used in the form of a sodium salt, made by adding one part of dry sodium carbonate to 3.6 parts of the acid. The diseases in which the salt was tried were croupy pneumonia, acute rheumatism, abdominal typhus, tuberculosis, erysipelas, acute endocarditis, and pericarditis, and the patients were from four to fifteen years of age, the dose given for patients up to six years old being two grains, and up to twelve years four grains. So far as could be ascertained from these experiments it appears that the new compound possesses some antipyretic properties, and also has some effect in increasing the blood pressure.

Dr. W. Leonard Braddon has pointed out (*Lancet*, March 17th, p. 513) that oil of peppermint possesses powerful antiseptic properties, which have been singularly overlooked. Koch, in his researches on charbon bacillus, found that of this drug 1 in 300,000 parts of liquid arrested the development of spores, and that the vapour very quickly killed both spores and bacilli. The results of a series of experiments made by Dr. Leonard led him to the conclusion that oil of peppermint is, within limits of time, one of the strongest and most reliable of antiseptic agents. Being stated to be absolutely harmless to the system in the largest doses it forms the safest, best, and most agreeable of all known antiseptics.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTIVEN, M.D.

Researches into the Pathological Anatomy of the Placenta, in Abortion. By Zinowief, St. Petersburg (*Centralblatt für Gynakologie*, February 25th, 1888).—The following are the results of the author's researches. Hyperplasia of the connective tissue occurs independently of hæmorrhagic deposits. Hyaline degeneration of the placental vessels has not been observed, but a periarteritis is described as the cause of the white patches. Interplacental hæmorrhage is described as diffused or circumscribed; in the latter case the blood fills the network of the connective tissue, and produces atrophy of the placental cells. These cells have been found transformed into a spindle shape. No special disorder of the endothelial cells has been observed. The author

describes a mucous infiltration of the deciduous cells and villi; also fatty degeneration of the same structures. Atrophy of the cells causes a granular appearance of these also. These changes in the cells are among the early steps to hydatid disease of the placenta. In retained placenta, after abortion, the author has found all the above pathological states of cells and villi.

Contribution to the Pharmacology of Cornutine. By Lewitzki (*Centralblatt für Gynäcologie*, February 25th, 1888).—1. In frogs, cornutine, in poisonous doses, induces excitement of the central nervous system, which issues in convulsions, besides which it exerts a special action upon the muscular substance, whereby the cramp of the limb is prolonged. 2. In warm-blooded animals (not impregnated), given in small doses, it effects stimulation of the vagus, with slowing of the pulse, vomiting, diarrhoea, etc. In large doses it causes clonic and tonic convulsions of a severe character, and death from paralysis of the respiratory centres. 3. In pregnant animals (dogs, rabbits, guinea-pigs) abortion is caused by its action on the lumbar region of the spinal cord. The researches of Jacob and Frommel have shown that the uterine contractions are clonic and tonic, and destroyed by division of the cord; in accordance with the conclusions of Von Robert. In women, cornutine seems to be the most certain agent for the exciting contraction of the uterus, whether impregnated or unimpregnated. Especially beneficial have been its effects in uterine hæmorrhage.

Researches on the Connection of the Hypoglossal Nerve in the Medulla Oblongata. By P. Koch, Copenhagen (*Fortschritte der Medicin*, Berlin, March 1st, 1888, from *Archiv. Anatomie*, 1887).—The author submits the following conclusions: 1. There is a connection between the hypoglossal nerve and the olivary body. 2. Stilling's nucleus is in the human subject the most essential part. Near to this is an accessory nucleus which, in birds, plays the most important part. 3. Around this nucleus there is no crossing of nerve fibres. 4. A system of longitudinal fibres, proper to the nucleus, connect the several parts of the hypoglossal nerve, while transverse commissural fibres bring the nuclei of the two sides into connection. 5. The fibres which pass from the nucleus into the nerve-centre, pass through the raphe and extend to the pyramidal tract. 6. It is doubtful whether any connection exists with the lateral columns or nucleus of the vagus, or even with the posterior columns.

On Neurasthenia (*Cleveland Medical Gazette*, Philadelphia, February, 1888).—Dr. Byford explains the etiology of neurasthenia as arising out of defects in the quality rather than of the quantity of blood, which admits of its becoming rapidly exhausted of the material necessary to restore functional action of the nerve-centres. Under this view, it does not seem that absolute rest is so important as full-feeding—the rest does not nourish the nerve-centres, but prevents their expending force as fast as they acquire it. The nerve-cells, Dr. Byford observes, become anæmic, thence nervous exhaustion and neurasthenia.

The Treatment of Writers' Cramp—Limbeck (*Fortschritte der Medicin*, February 15th, 1888).—In a case of writers' cramp, in which massage, electricity, and other means had been unsuccessfully employed, great benefit had been derived from the use of a splint extending to the index and forefinger from a bracelet firmly attached to the forearm, so as to prevent flexion of the hand.

On the Administration of Creasote in Phthisis.—Sommerbrodt and Hopmann (*Fortschritte der Medicin*, March 1st, 1888), reasoning from the antiseptic properties of creasote, the authors have administered this medicine in phthisis, in large doses, continued for many months, during the last six or seven years with satisfactory results.

II.—NOTES FROM RUSSIAN JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

Strychnine in Alcoholism.—At a meeting of the Novgorod Medical Society, Dr. E. I. Lebedeff communicated an interesting case (*Proceedings of the Novgorod Medical Society*, 1887, p. 33) of acute alcoholism of a (so to say) therapeutic origin, in which he had successfully used tincture of nuxvomica. A previously non-drinking lady, suffering from a severe puerperal parametritis of two months' standing, was advised by her former medical attendant to take occasionally about half a wineglassful of port wine or vodka (aquavit), on account of paroxysms of an excruciating pelvic pain. Since the pain was almost incessant, while, on the other hand, the remedy recommended gave actually a marked, though temporary relief, the lady soon reached a daily dose amounting to about a half a bottle of port wine or brandy. By the end of a month there appeared sleeplessness, hallucinations of sight and hearing of a terrifying character, trembling of the tongue and limbs, an uncontrollable incessant craving for drink—in short, there developed a typical delirium tremens. Frequent doses of tincture of

nuxvomica (the exact dosage not given), and hydrate of chloral as a hypnotic at bedtime, removed all the symptoms (including craving) as swiftly as radically.

Dr. Serghei V. Iaroshevsky, of Samara, publishes his second important paper (*Meditsinskoié Obozrenië*, No. 2, 1888, p. 194) on "Antagonism existing between Alcohol and Strychnine." His first communication on the subject (made at the Moscow General Meeting of Russian Medical Practitioners in 1886, and briefly alluded to in the *Provincial Medical Journal*, August, 1887, p. 372) dealt with clinical and experimental questions concerning sub-acute and chronic alcoholism, and the influence of strychnine on the development of toxic phenomena. A scarcely deniable great practical importance of the matter will probably excuse our returning to the author's former paper, and adducing some interesting details. The first series of his investigations consisted of six experiments (on dogs) of from thirty to 107 days' duration. Three animals (an adult bitch and two puppies) received alcohol alone. The bitch (weighing sixteen pounds) took in all forty-five ounces of a 65 per cent. alcohol (the daily dose varying from half to three ounces), and died on the thirtieth day of the experiment. The puppies, aged twenty-six days, and weighing each about three pounds, took—one eleven, the other twenty drachms of a 42 per cent. alcohol (in the daily dose of from two to four drachms), and both died on the seventh day. The other three dogs (a pregnant bitch, weighing twenty-eight pounds, and two puppies, aged twenty-six days, and weighing about three and a half pounds each) received simultaneously alcohol and strychnine, the latter being injected under the skin in the form of a solution of one grain to one ounce of water. Only one of the animals died spontaneously (on the twenty-eighth day); it was a puppy, which had received in all 146 drachms of a 42 per cent. alcohol (in the dose of from three to twelve drachms a day), and 140 drops of the strychnine solution. The other puppy took also 146 drachms of a 42 per cent. alcohol (in the dose of three to twelve drachms a day), and 140 drops of the alkaloid (in the daily dose of from four to twelve drops). It remained quite well all through, and was killed on the twenty-ninth day of the experiment. The bitch received 706 ounces of alcohol (in the dose of from one to seventeen ounces a day), and 594 Pravaz's syringefuls of the strychnine solution, or 19.8 grains of the alkaloid, the dose varying from one to twelve syringefuls. On the fifty-sixth day the animal gave birth (at full term) to seven healthy puppies. The dog was killed in apparently good health on the 107th day. A direct antagonistic action of the alkaloid was especially strikingly demonstrated in this animal by two controlling experiments. When the dog received alcohol alone in the amount of five ounces of a 65, and twelve ounces of a 42, per cent. solution, a heavy intoxication at once made its appearance; but when the same quantities of the same alcohols were administered simultaneously with the injection respectively of five and eight syringefuls of the strychnine solution, not a slightest sign of any alcoholic poison could be observed. The same may be said in regard to the last week of the dog's life, when the animal was taking daily as many as seventeen ounces of alcohol, and at the same time was receiving twelve syringefuls of the strychnine solution a day. The same could be repeated also in regard to both of the puppies. The results of the *post-mortem* examination in the first group of experiments strikingly differed from those in the second. In those animals which had taken alcohol alone, there were present an intense congestion and cedema of the meninges and brain, flattening of cerebral convolutions, slight dropsy of cerebral ventricles. Meanwhile, in the two killed dogs there was detected (microscopically) nothing abnormal, beyond a slight anæmia of the cerebral substance, as well as of the kidneys and gastro-intestinal mucous membrane. Only in the fatal case of this group there were found slight hyperæmia and cedema of the brain and its membranes, and gray hepatisation of a pulmonary lobe.

In his second paper Dr. Iaroshevsky says that he has carried out two additional experiments for elucidating the action of strychnine in acute alcoholism. He took two healthy young dogs, weighing sixteen pounds each, and gave one of them three and a half ounces of a 62 per cent. alcohol in the course of about ten minutes. After the first ounce a typical intoxication, and after two and a half ounces an extreme prostration, appeared; after another ounce the animal immediately expired. At the *post-mortem* examination, there was found intense hyperæmia of almost all organs of the body, but especially of the brain and its membranes, the cerebral substance being studded with numberless punctiform hæmorrhages. To the other dog the author administered, by portions, nine and a half ounces of the same alcohol and eight syringefuls of the strychnine solution, all in the course of twenty minutes. The first signs of intoxication (slight unsteadiness and weakness of the hind legs) made their appearance only after the ingestion of full five ounces; after eight ounces had been taken, prostration developed, the animal dying two and a half hours since the beginning of the experiment. The necropsy revealed the presence of a compara-

tively slight hyperæmia of all organs, and slight œdema of the brain and its meninges; punctiform extravasations were almost absent. The remaining part of the paper is devoted to a detailed description of the results which were given by the microscopical examination of various organs in all the dogs experimented upon. The following table allows the reader to make an instructive comparison between the two groups:

ALCOHOL ALONE.

(One Experiment.)

Brain and its Membranes.—Intense capillary hyperæmia, with extravasations. Swelling and fine granularity of nerve-cells. Their nuclei are shrunken, fringed, granular, take in dyes but slightly, or do not take at all.

Liver.—Capillary congestion. Hepatic cells swollen; some are opaque, some granular. Lobuli indistinct. Biliary ducts narrowed.

Kidneys.—Congestion opaque. Swelling of the epithelium.

Heart.—Normal.

ALCOHOL AND STRYCHNINE.

I.—ACUTE POISONING.

(One Experiment.)

Brain.—Capillary hyperæmia comparatively slight. Extravasations nearly absent. Nerve-cells and their nuclei normal.

Liver.—Congestion. Hepatic cells normal.

Kidneys.—Some congestion. The epithelium normal.

Heart.—Normal.

II.—SUB-ACUTE POISONING.

(Three Experiments.)

Brain.—Dilatation of peri-vascular spaces, with leucocytes accumulated in diverticula. Incipient hyaline degeneration of vascular walls. Nerve-cells: intense granularity of the protoplasm; generally, the same phenomena as in an acute form, but in a much more pronounced degree.

Liver.—Hepatic cells somewhat shrunken, dark granular; others opaque and swollen. Between them there are seen foreign elements, in the shape of opaque, spheric, and oblong bodies.

Kidneys.—Epithelium opaque, swollen, granular. Tubular lumina narrowed or obliterated. Malpighian bodies separated from Bowmanian capsule by exudation or a vacuole. Their capsules thickened.

Heart.—Normal.

(Two Experiments.)

Brain.—Nothing abnormal, except a slight opaque granularity of some nerve-cells.

Liver.—No congestion. Nothing abnormal, beyond a few opaque, granular hepatic cells.

Kidneys.—Epithelium normal. Malpighian bodies present some morbid changes resembling those met in pure alcoholic cases, but in a by far slighter degree.

Heart.—Normal.

ALCOHOL AND STRYCHNINE. III.—CHRONIC POISONING.

(One Experiment.)

Brain.—Nerve-cells opaque, occasionally with slight granularity. Some nuclei, slightly granular, somewhat shrunken, take in dyes but very badly. The wall of capillaries opaque, pale, closely adherent to the adjoining cerebral tissue.

Liver.—Some hepatic cells are shrunken, and separated one from another by small heaps of leucocytes. Some cells contain fatty granules.

Kidneys.—Tubular epithelium somewhat swollen, granular. The membrane of urinary tubules is thickened. Malpighian bodies sometimes shrunken, and surrounded with leucocytes.

In other words, the cerebral nervous system, which undergoes very pronounced morbid changes under the influence of alcohol alone, remains almost intact when strychnine is simultaneously used. As regards the liver and kidney, the antagonistic action of the alkaloid seems to be comparatively less powerful; however, it somewhat fails only in chronic alcoholism, and even here it unmistakably retards or inhibits the development of morbid changes (cirrhosis). The general conclusions drawn by Dr. Iaroshevsky from his researches are these:—
1. Strychnine most decidedly enables the animal organism to receive large quantities of alcohol for a prolonged period, without any apparent injury to the central nervous system. 2. Strychnine can be recommended in all forms of alcoholism. 3. The best results, however, may be expected in the so-called neuropathic or nervous variety of alcoholic intoxication. The drug will prove, probably, less successful in simple chronic alcoholism with classical hepatic cirrhosis.

[Since the literature on the use of strychnine in alcoholism seems to rapidly grow into something like a prominent chapter in therapeutics, it might prove of service for a future historian of medical science if we chronicle on these pages the fact that it was Dr. Iaroshevsky, and not Dr. N. M. Popoff, who first in Russia (in August, 1885) began to treat dipsomania by strychnine, and that with brilliant results. According to Dr. Iaroshevsky's statement in the *Meditsinskoi Obozrenië*, No. 4, 1887, p. 334, the first of the two cases published by Dr. Popoff (see the *Provincial Medical Journal*, August, 1887, p. 372) was previously under his care, Dr. Popoff only continuing the method of treatment resorted to by Dr. Iaroshevsky. During a discussion which followed Dr. Iaroshevsky's first communication (*Proceedings of the Second Meeting of Russian Practitioners at Moscow*, vol. 1., sect. vii., p. 10; and *Meditsinskoi Obozrenië*, No. 4, 1887, p. 321), Dr. Zakhar A. Zavadsky, of Kürsk, stated that, according to his personal experience, strychnine was an excellent remedy for dipsomania and acute alcoholism (see a paper of his in the *Provincial Medical Journal*, August, 1887, p. 372), but it proved of little use in chronic varieties. He never saw any improvement in organic lesions (cirrhosis, etc.) in chronic patients

treated by the alkaloid. Dr. Stanislav I. Tchirvinsky, of Moscow, thought that an antagonistic effect of strychnine in regard to alcohol should be sought in its stimulating action on the medulla oblongata and spinal cord (as manifested by rise of blood-pressure, retardation of the pulse, etc.), in a direct opposition to alcohol which possessed a paralyzing action on the centres named. Dr. George A. Carrick, of St. Petersburg, said that Dr. Iaroshevsky's experiments on animals did not yet justify any direct clinical deductions for a therapeutic application in man, since the action of alcohol in man was considerably different from that in lower animals. Professor Victor S. Bogoslovsky, of Moscow, warned against a wide public propaganda of strychnine as an antidote for alcohol; since, on one side, it could lead to a further increase in alcoholic excesses, while, on the other, it could give rise to habitual "strychnophagia" or "strychninism," analogous to habitual cocaineism, morphinism, opiophagia, etc. Entirely differing from Professor Bogoslovsky, Dr. Zavadsky emphatically expressed his belief that nothing but good (including a rise in human morality) could be expected from an antidotal use of strychnine. He quoted, in support, a recent case of his own, where a hopeless drunkard, cured by the alkaloid, had become an excellent husband and father. In the *London Medical Record*, December, 1887, p. 543, there may be found a strikingly successful case, published by Dr. Berblinger, of Riga. A preliminary note on strychnine in alcoholism, by Dr. Korona, of Tiflis, is reported in the *London Medical Recorder*, March, 1888, p. 16.—*Rep.*]

III.—SELECTIONS FROM SPANISH AND FRENCH MEDICAL JOURNALS.

TRANSLATED BY DR. G. CADOGAN-MASTERMAN.

Rossbach's Chair in the Treatment of Pulmonary Emphysema (*Revista de Ciencias Médicas*, Barcelona).—In pulmonary emphysema, or, as it is popularly misnamed, asthma, the distress of the patient is chiefly felt in the act of expiration. The over-distended cells of the lungs have lost elasticity; the vault of the diaphragm is lowered, and the ribs, in their typical barrel form, act at a mechanical disadvantage; therefore, the residual air is always in excess, and it needs much more than the gentle, natural fall of the thoracic walls to expel the air which in health is expired so imperceptibly. The idea of mechanically helping the sufferer is an old one, and almost instinctive, and has usually been performed by an attendant pressing with his hands the sides of the chest as the patient out-breathed. Gerhardt seems to have been the first who reduced this idea to a system, and trained nurses in the art of rhythmically compressing the thorax at the right moment and for as long as it was necessary. And this method, in spite of its obvious imperfection and inconveniences, has given excellent results. Practised twice or thrice a day, for only twenty or thirty respirations each time, at the end of a few weeks there has been noted a considerable augmentation in the vital capacity of the lungs, a diminished rate in breathing, an evident elevation of the diaphragmatic dome, and increase in the area of the heart's dulness. For the hands of an attendant Dr. Feris substituted a thoracic belt, which could be used effectively and with less fatigue, but still with the same defect that the intermission and duration of pressure were not regulated by the patient, but by a possibly inattentive nurse.

Professor Rossbach, of Jena, has devised a chair which satisfies every condition when used by the patient himself, or, by reversing the position of the levers, may be worked by a careful attendant sitting behind and watching the descent of the shoulders as the signal for turning the rollers. The chair is an ordinary wooden one, without arms¹ and with a straight back; the seat is prolonged backwards about three inches, and two horizontal brackets are attached to the top rail correspondingly. These support two upright wooden cylinders nearly three inches (seven centimètres) in diameter and as long as the back of the chair, and placed just outside its outer rail on each side. They revolve on iron pins which pass through the projection of the seat and the brackets respectively. At the bottom of each is attached a lever, or wooden handle, of convenient length for the patient to grasp with his arms extended, and, when drawn forwards parallel to each other, the cylinders make a quarter of a revolution. A broad band of strong webbing passes across the chest of the seated patient, and is attached by eyelet holes to a row of studs on the inner face of the two rollers; therefore, on pulling the handles forward, the thorax is compressed, and to any extent which may be thought necessary. As a matter of detail, the bandage divides in the middle and is fastened in front exactly as is done in ladies' corsets, by a row of studs and steel loops. Provision is, also, made for different sized chests by such simple expedients as several rows of eyelet holes, or buckles attached to iron rods, over which the ends

¹ I find one of the rush-bottomed chairs so commonly used in churches answers capitally.—G. F. C.-M.

of the belt are sewn. This belt is a foot in breadth, and is kept in place by two bands passing over the shoulders and buckled to the top rail of the chair. It may be most conveniently made in three pieces for more ready adjustment to the varying conoidal form of patients' chests.

The apparatus is used as follows: The patient seats himself well back in the chair, the levers are drawn outward, and the belt is comfortably adjusted so as to press equally over the thorax, and is fastened to the rollers on either side. Then, extending his arms, he grasps the handles, takes a deep breath, and, as expiration commences, pulls them slowly forward; that act completed, he pushes them somewhat quickly to their first position, takes another deep breath, pulls them gently together again as far as he finds necessary, and so on *da capo*.

It will be at once seen that in this way the movements of the arms coincide with and assist those of respiration; throwing them back helps in filling the chest, and in pulling the levers forward the *pectorales* are relaxed and the ribs depressed at the same moment. We have, in fact, artificial respiration with an automatic operator. The movements are timed and persisted in as long as the physician may have directed—fifteen times per minute, and for ten minutes three times a day, is generally prescribed. The advantages of this apparatus are, that it equally compresses the whole of the chest; that the patient can use it, when once adjusted, alone either by day or by night; that any village carpenter can make it, and that its cheapness places it within the reach of all. The following cases will illustrate its usefulness:

N. L., æt. fifty-six years, a workman in the Arsenal of St. Petersburg, was twenty years in the army, but since 1875 has been working as a labourer, chiefly in moving and carrying very heavy weights. About eight years ago he began to suffer from cough and difficulty in breathing, which disabled him from time to time. In the beginning of October, 1887, he entered the Military Hospital and came under treatment. He is of middle height, muscular, fairly well nourished, radial arteries thickened and incompressible, lips and hands dusky, thorax barrel-shaped, with flattened subclavicular spaces. The movements of the ribs were exceedingly small even during forced inspiration. Auscultation showed general dilatation of the lungs and great encroachment on the cardiac and hepatic regions; there was dry ronchus, and prolonged expiratory murmurs. The circumference of the chest at the nipple line during quiet inspiration was eighty-seven centimètres; forced, ninety centimètres; forced expiration, eighty-six centimètres. He was kept at rest for five days. Pulse was then sixty-five; respiration twenty-four per minute; vital capacity 2,800 to 2,900 c.mm. (the normal should have been, according to Fabius's tables, 3,445 c.mm.). On the 11th of November treatment with Rossbach's chair was commenced, 100 to 200 compressions, at first twice, then three times a day. Before the end of three weeks the patient found himself very much better, and the vital capacity had already advanced to 3,400 c.mm. The expiratory force was eighty mm.; the breathing had fallen to eighteen or twenty times per minute; the liver had receded to its proper site, and the heart's dulness correspondingly increased. He could breathe without difficulty, run easily upstairs to the second floor of the hospital; all œdema had disappeared, and he could work as well as of old. He was discharged cured after six weeks' treatment.

S. S., æt. sixty-six years, porter, like the last had been twenty years in the army, and of intemperate habits. One of his duties had been to carry firewood to the top stories of large houses in St. Petersburg, and under the strain his health had broken down. He has suffered some years from "asthma" and cough. He is described as "a tall man," 170 centimètres (5 ft. 6½ in.) in height, thin but muscular. The lips and hands cyanotic, arteries enlarged and tortuous. Vital capacity 2,300 to 2,400 c.mm. (it ought to have been 3,600); pneumometric force fifty mm. in inspiration, sixty mm. in expiration; chest expansion four c.m. It is unnecessary to give the various chest measurements. On the 12th of November treatment in Rossbach's chair was commenced. At first the patient was exhausted after thirty or forty respirations, but the number was gradually increased to 200 before tiring him. At the end of six weeks there was great improvement in all respects. The chest measurements were much the same, but the vital capacity had increased to 2,850 c.mm., and the expiratory force to eighty or eighty-four mm., and the breathing fallen from thirty-two to twenty-four per minute; and the man could run up a flight of stairs which he could at first ascend only slowly and pantingly.

S. H., æt. fifty-six years, a printer, of steady habits, "medium height, 159 c.m." (5 ft. 2½ in.), and somewhat emaciated. Vital capacity 1,600 to 1,700 c.mm. (normal 2,850); inspiratory energy forty-four mm., and expiratory, fifty mm.; chest expansion, four c.m.; rate, thirty to twenty-eight; pulse, seventy per minute. The liver, as in the preceding cases, was depressed below the thoracic margin. After a month's treatment the vital capacity has increased to 2,000 c.mm., expiratory energy to 60-62 mm., chest expansion to five c.m., whilst the respiratory rate had fallen to twenty-four per minute and the liver had receded within the ribs.

The preceding cases are sufficient to show the value of this machine in the treatment of a very distressing complaint, which is common amongst the labouring and especially the intemperate poor, and one which can be used simultaneously with other forms of physiological treatment—such as in Waldenburg's cabinet—or conjoined with the use of expectorants and cardiac tonics.—(*Vrach.* 1888. No. 3.)

Episodes in Medical Life—A Consultation (*Journal de Médecine de Paris*).—"I was attending, some twenty years ago, the only son of a rich manufacturer, a lad of about sixteen or seventeen years, for a slight laryngeal affection. In all other respects he enjoyed excellent health, and it was clear enough that the throat trouble was purely local; nevertheless, it was one bitter drop in the overflowing cup of happiness in the family circle. His parents were always dreading that it would end in bronchitis or a decline. The slightest cough, the least ronchus, raised the grim and terrible spectre of phthisis, and the lad was to die incontinently. I used to examine his chest with the most anxious and minute care, but could discover nothing to justify any fear or even doubt of the correctness of my diagnosis; but, in spite of balsamics and sedatives, the slightest exposure to cold would cause a little hoarseness, a transitory cough, often without any reason whatever except, it seemed to me, the excessive precautions taken to avert it. The rooms were always too hot, the lad was overclothed—could not stir without a respirator or voluminous wrappers; but when I ventured to hint at this the invariable reply was, "Ah! doctor, if we did not take all these precautions how long would he be with us—the dear child is so delicate?" And nothing I could say would alter their opinion.

One day, when they had been worrying themselves more than usual about the young fellow, the mother, whilst walking with me to the door, said: "Doctor, you know we have the utmost confidence in you; we carry out your instructions to the letter; but our dear child—" "Yes, madam; only you will wrap him up in too much cotton wool." "Well, perhaps you are right; but we are so very anxious—he is our only son. Now, would you mind our asking for the opinion of some famous specialist?" "Nothing would be easier or better. Pray, whom would you like, and when shall we see him?" She mentioned a name well-known in Paris; certainly not of one I should have chosen, for his fame was more social than professional. However, there was no reason why I should decline to meet him, and the interview was arranged. The great man arrived, and was introduced to the patient. "What!" cried he, in theatrical tones, "Is it that fine lad we are to consult about? That superb fellow, in such perfect condition? Come! confess, madame, that you are only making fun of us!" "Well, I admit appearances are in his favour, and I hope his condition is not serious; but he is always losing his voice—always coughing—and if we were not to take care—" and a flood of tears drowned the rest of the sentence. "But, my dear lady, why distress yourself? All may be well. Let me hear from my *confrère* the symptoms." I gave them in a few words. "Well, well, there seems to be nothing serious; but we must examine the chest with the utmost exactness to decide that." "Pardon me," interrupts mamma, "but will you allow me to remain in the room?" "Of course, madame; you have a sacred right to remain: Pray, sit down." And then he begged me to commence the examination. I percussed with minute carefulness every part of the thorax, and, as before, could really find nothing abnormal. "There, you perceive that I have tested with exactness, and the resonance is everywhere perfect." I said this as a matter of form, for I had noticed that the doctor had not paid the slightest attention to my proceedings, but was talking in low tones to the mother the whole of the time. "Ah, well, now it is my turn," said he, and with impressive care placed the lad in position; not, as I had, with the arms crossed on the chest, but stiffly extended. In place of telling him to count "thirteen to sixteen" he gave him a book and directed him to read a dozen lines, and then to sing the gamut, an octave and a half. The mother was watching all this with admiring eyes, and devouring every detail. "Ah! humph!" said the oracle, "it seems there is something—but most difficult to differentiate. Let us hear what percussion yields." And his style was enchanting. Every tap with the fingers was given with a flourish and a graceful sweep as if he were doing the three-card-trick at a fair. There was a moment of indecision and then, with a covert smile, turning towards me he murmured: "There it is; listen, my dear young friend," as he beat his digital drum, now on this side, then on that, "Tick-tock, tick-tock—now, do you not hear it? There is a very appreciable difference in resonance. When I say 'an appreciable difference' I do not say an enormous one—no—but there it is!" "For my own part, my dear sir, I cannot detect the slightest difference." "Oh, very likely, but there it is. But now, come, let me convince you: I will turn my back to the patient, and you shall percuss, and I will tell which side you are tapping upon. You must really do me this favour." He turned round, and I percussed as equally as possible the two sides. "You are on the left side." He was quite right! In a moment, however, my surprise was

changed to admiration. The trick was obvious enough, but done so neatly, with such perfect aplomb that I was duped even whilst taking part in it. He had turned his back to us, but was looking into a large mirror above the console which faced him!

I said nothing; indeed, the tables had been turned so cleverly that I had nothing to say. "Madame, I must not alarm you," he observed, impressively, "these delicate gradations in tone can only be heard after immense practice, only by those who examine a stream of patients—but there is something on the left side of your son's chest—nothing serious,—so little indeed that even my young friend here could not detect it; but there it is. And, now, permit us to consult together as to the treatment."

When we were alone I again expressed my incredulity. "Tut, tut! my dear young friend, you have not yet grasped the situation. Now, here you have a lad who coughs, and has been hoarse for a long time—then how the deuce can you get over that fact by telling the parents that there is no cause for it! Very likely there is nothing the matter with him; but, why does he cough?" "That was exactly what his mother said to me." "There you are—and mamma was quite right—there must be some cause for it. We may not be able to lay our finger upon it, for we must examine and understand our patients thoroughly very often before we can make out their ailments; and then one finds it, because, you see, we are expected to discover it." "But, suppose there really is nothing." "Nonsense, there always is—but even if there were not—we are equally bound to find it; for if you tell these anxious people, 'I can find nothing wrong,' they simply put that down to your ignorance, and send for somebody else, who has knowledge enough of human nature or sufficient *savoir faire* not to be embarrassed by so trifling a difficulty. Now, do you see my meaning?" "Theoretically there is nothing, practically there is." "If you like to put it so; but I assured you that there is—and there really is—a little difference in resonance. The mamma heard the remark; she has not the remotest idea what it means, but she is perfectly happy now that the cause of her darling's cough has been discovered, because she thinks, the cause being known the cure must follow; and the more unintelligible the explanation, the more convinced is she of its correctness. One may cure, you know, a difference in resonance, but how can you pretend to cure a person whom you declare has nothing the matter with him?" I began to understand. "Now I admit this is not science—" "Nor what we were taught in the schools." "By Jove, I should think not; but it is a good working rule—smelling a little perhaps of the shop and the lawyer's tape—but if our patients are satisfied, nay! made happy, what does that matter? What is the art of the dramatist in his most thrilling situations but a trick; the skill of the author, a trick of his brain; of the artist in creating his *chefs d'œuvre*, a trick with the paint brush?" "Well," a little sadly, "I daresay you are right." "Of course I am. I am a cynic, but I succeed. I have had the honour to be asked to meet you to-day—and now for treatment."

A little delicate counter-irritation, a trace of arsenic in syrup of orange peel, sufficed.

As I accompanied this truly great man to the door, he smilingly observed, waving my compliments away, "You are too modest, my ingenious young friend; you have already the science of medicine at your finger ends—why not acquire the art also? Adieu."

"MORAL."?—Oh, well, one always learns something at a consultation!

IV.—OBSTETRICS AND DISEASES OF WOMEN.

Uterine Moles. By Edward Rosenthal, M.D. (*Journal of the American Medical Association*, March 3, 1888, Chicago).—Obstetricians divide moles into two great classes: *a*, the false; *b*, the true moles. True moles are subdivided, as regards their physical character, into fleshy and vesicular or hydatidiform. The fleshy are again divided into fatty, carneous (steinmole); etc. Moles have been designated by different names: moon-calf (Mondkalb); devil's blood (Teufelsbrut); wind-egg (Windei); sun child (Sonnenkind); Neirenkind, Kielpopf, Missgeburt, etc. By the profession they are designated by their contents: blood mole (Blutmolen); water mole (Wassermolen); air moles (Luftmolen); hair mole (Haarmolen); cartilaginous mole (Fleichenmolen); bone mole (Knochenmolen); and calcareous mole (Kalkmolen).

a. Spurious Moles.—Mauriceau believes that moles could not exist without impregnation; that it was always the offspring of intercourse. In his 105th aphorism (*Traité des Maladies des Femmes Grosses*) he says: "Les femmes n'engendrent jamais des moles, si elles n'ont usé du coït." This Alexander Milne, of Edinburgh, cannot subscribe to, believing that cases occur; nay, more, having met with them, where fleshy masses have been expelled from the uteri of women who certainly never had connection. If virgins expel such things, then, they are not to be impeached; to do so would be unjust. Various substances, organized or unorganized, may be discharged from the uterus of the virgin; such substances as clots of blood, membranous shreds, or even whole

membranes, as well as fibrinous materials. These may even have the shape of the uterine cavity, and may come away naturally or must be removed; and which have nothing whatever to do with fecundation, and are termed spurious moles. Their significance is of some importance from a medico-legal view, and the utmost care should be exercised in differentiating these false moles from true ones. Difficulty may arise when the discharged tissue is the membranes of membranous dysmenorrhœa, where this tissue may be mistaken for true decidua membranes. The circumstances attending each case should receive the earnest scrutiny of the attending physician. All circumstantial and direct evidence should be gathered: were there any previous attacks? note the absence of the signs or symptoms of pregnancy, and so on. Examine the discharged mass; should this happen to be complete, we may find the opening of the Fallopian tubes and that of the cervix, which is never observed in true decidua. The microscope, however, will determine the presence or absence of the fecundated ovum. Blood clots, polypi, and small fibroids or portions of large ones should not be difficult of recognition by naked eye or microscopic examination.

b. True Moles.—True moles are always the result of impregnation. The villi of the chorion may become distended with fluid collecting within them, causing them to swell and assume the form of rounded vesicles comparable to gooseberries or grapes, resembling hydatid vesicles, and on account of this analogy they were for a long time supposed to be true hydatids. Or an extravasation of blood may take place between the maternal and foetal structure of the fecundated ovum or into the tissue of the latter, producing a fleshy mole. The embryo may become mummified, or may speedily disappear in the early stages, and then we meet only with the membranes or appendages. Two chief varieties of true moles are at present recognised, namely: 1, the fleshy; and 2, the vesicular or hydatidiform mole.

Etiology.—Extravasation of blood between the maternal and foetal structures of the fecundated ovum, or into the tissues of the latter appears to be the active agent in the production of the fleshy mole, which is the most frequent form.

Symptoms.—The immediate symptoms are those of a threatening miscarriage. Absence of the placental soufflet and of the positive signs of pregnancy are among the signs.

Course.—The course of the molar pregnancy of the fleshy variety is variable. Generally at three months, nature seeks to throw off the mass. Hæmorrhage comes on about this period, and then it is simply a question of time when the uterus expels its contents.

Diagnosis.—The diagnosis of the fleshy mole I should deem impossible. Suspicion may arise when the patient has had one before, but as regards positiveness, I think it out of question. It can only be made when you have the tumour in your hand.

Prognosis.—All the cases here quoted ended favourably. Prompt treatment should be the rule. Should danger arise from the excessive hæmorrhage, the tampon is always a safe and efficient remedy. Some cases of extra-uterine moles which authorities quote, that have been met with in the ovary and abdomen, and the cyst given way, causing death, are of course unfavourable. Sometimes these cysts have opened into the bladder or bowels; the result being the same. Still, the same chances which extra-uterine pregnancies have in antiseptic surgery extra-uterine moles may have; and the prognosis modified. These cases are, happily, most rare. Wilton (*Lancet*, February, 1840) relates one case. Peritonitis may result from the misuse of instruments, causing death. Hæmorrhage might, and pyæmia and septicæmia, etc., may cause death.

Pathology.—The pathology of fleshy moles is still shrouded in obscurity. Heart disease, causing an effusion of blood; again, syphilis and other blood dyscrasie, appear to exert an influence, and perhaps the same may be said of acute specific diseases where they fail to excite abortion. Whatever may be the exciting cause, when once blood has been effused into or between the foetal and maternal structures, the vitality of the embryo is speedily compromised. The common result is abortion; but, should not the whole be thrown off, growth may take place in the remaining tissue; while the effused blood becomes organized and gives bulk to the mole. In a case of cancer of the ovary, posted by a friend, I removed some time previous what I termed a retained placenta, which was in the uterus of the unfortunate woman five months. The maternal placenta is formed by the decidua serotina. The foetal placenta is formed by the villi of the chorion, which, having originally covered the entire surface of the ovum, atrophy over the major part of surface, while they ramify and develop, *ad infinitum*, at the point corresponding to the serotina, where they become imbedded and constitute the vascular mass known as the placenta. To study changes in the chorion amounts to studying the lesions of the placenta, and the reverse. Now, these changes may relate to each of the placental elements, *i. e.*, the vessels and the villi. Not infrequently a considerable effusion of blood takes place immediately beneath the amnion encroaching greatly upon and sometimes rupturing the amniotic sac, and Cazeau (1876, page 578) gives his description of a fleshy mole as follows: "It

may further happen that the placenta, maintaining its vascular adhesion with the internal surface of the organ, continues to develop after the child's death, the cord and fœtus becoming atrophied, and then completely destroyed; or, indeed, the ovum may rupture, and the little product escape, leaving the membranes behind. These envelopes may undergo various modifications, but the most common is the morbid product known as a fleshy mole." The inner aspect of the cavity then presents an irregular nodular appearance, and is of deep red, almost black colour. When the nodules are incised they are seen to be composed of firm blood clot. The fetal surface contains numerous blood cysts.

Vesicular Mole.—The vesicular, hydatid or hydatidiform mole is the better understood, if not the more important variety of the true mole, and has received the most attention of the pathologist. I have seen it but three times, twice in one person. I will relate the cases here. We are still not assured whether the cause of the variety is primarily in the ovum, or in the diseased decidua. The cause may lie with the mother; Virchow attributes it to endometritis.

The symptoms are those of ordinary pregnancy. There is, however, a tendency to watery and sanguineous discharges, and sometimes small vesicles come away, when the diagnosis is clear.

Pathology.—The name "hydatid" mole is erroneous and misleading. There are no true hydatids or echinococci in it; the physical arrangement of the vesicles is different. True hydatids are closed sacs, contained one within another, while the vesicular mole is formed by sacculi growing from one another. It was formerly supposed that they grew from a common stalk, and they were likened to a bunch of grapes or currants; but for the reason given above the simile was imperfect. The vesicles vary in size from a chestnut to a pin's head or less; usually they are about the size of small currants, and as a few may from time to time escape accompanied by more or less sanguineous discharge, Gooch's simile of "white currants floating in red currant juice," is a very apt one. Dubois and Desormeaux describe three varieties of hydatidiform moles. 1. The embryonal hydatid mole. 2. The hollow hydatid mole. 3. The hydatid mole *en masse*. The first variety consisting of a membrane, vesicular on its outer surface, with an internal cavity containing a fœtus or parts of one, and possible fluid. The second kind is like the first, save that its cavity contains only fluid, and possibly a remnant of the umbilical cord, the fœtus having been dissolved. The third variety is distinguished by the enormous development of the hydatid bodies, and the more or less complete effacement of the central cavity formed by the amnion, the place of which is taken by a mass of soft, yellowish, spongy tissue.

The authorities agree that vesicles grow from the chorionic villi. There is no new formation, but excessive and erratic development, Mettenheimer, Paget, Barnes, Virchow and others, concur in this view. Whether the change is the cause or the consequence of the death of the embryo is unsettled. It may be some innate morbid condition of the ovum, or some acquired defect. Dr. Hewitt thinks that the starting point of the abnormality is the death of the fœtus rather than this latter is the result of the degeneration. Leishman points out that the period within which degeneration of the chorion villi may originate does not extend probably beyond the tenth week, that being the period of greatest activity in the growth and multiplication of the villi. Later on when blood vessels have occupied the bulk of the villi this kind of degeneration seems capable of formation. The probabilities therefore are in favour of the formation taking place in the first chorion or vitelline membrane. Normally, only those villi that correspond to the placenta develop progressively; but if a pathological condition supervenes very early in pregnancy, they are proliferate and become hyperplastic. Abortion usually follows, but it may happen that the placenta develops normally, only a certain group of villi becoming hydatid. Usually, however, the affection is situated just at the placental site, though only a portion of the cotyledons may be affected. In any case the affection begins as a multiplication of nuclei and cells. The theories concerning the vesicular mole may be summed up as Duchamp says, in the following propositions: 1. The vesicular mole is entirely independent of pregnancy. 2. The vesicular mole increases under the influence of pregnancy, but it is not due to a disease of the egg. 3. The vesicular mole is due to a change in the product of conception, from *a.* alteration of the vascular wall (Cruveilhier); *b.* alteration of the lymphatic vessels; *c.* dropsy of the chorinal villi (Robin, Cayla); *d.* Myxomatous degeneration (Virchow and the Germans, Ercolani, Damaschino, Cornil, Ranvier, Hirtzmann, 1874, Josephson, 1879). Of these the theory of Virchow is the accepted one, for the following reasons: 1. The normal villus contains mucoid tissue; it is not astonishing that it should hypertrophy. 2. The vesicular fluid contains mucin. According to Gscheidlen, it is composed of chloride of sodium, 3.34, phosphoric acid, 0.74, albumin, 6.12, mucin, 2.94, salts, 6.25.

V.—OPHTHALMOLOGY.

The Dangers of Simple Extraction of Cataract.—Derby, of Boston, in the *Boston Medical and Surgical Journal* of February 28, 1888, calls attention to the dangers of cataract operations, as follows: The question as to what operation should be performed in an ordinary case of senile cataract is once more a prominent subject of discussion. At the late meeting at Heidelberg, as well as at the one held at New London, this matter engrossed much attention. More recently, Professor Schweigger, of Berlin, has published in Knapp's *Archives* an article on the return to the flap operation, in which the performance of iridectomy, the "needless maiming of the iris," as the author expresses it, is strongly denounced. The question at present under discussion is, therefore, the following: Do the modern discoveries of a reliable myotic, of an efficient local anæsthetic, and the adoption of antiseptics, justify a return to the principle of extracting senile cataract without the performance of iridectomy? May not the operation, however, be restricted to certain cases? and are there not certain special rules to govern the after-treatment? The writer has laid down the following principles for his own guidance: 1. He would reserve simple extraction for those cases in which the cataract is ripe, the nucleus large, the patient tranquil and amenable to discipline. 2. After the operation, the application of the bandage should be slightly delayed, the object being to ascertain whether the iris, once replaced, shows any tendency again to prolapse. If it does so, it is to be at once excised. 3. Eserine is to be applied directly to the eye immediately after the operation, and dropped in the inner corner of the eye, without separating the lids (as recommended by Schweigger) for the three following days. 4. Greater quiet on the part of the patient is to be insisted on than has been the case after the operation of Gräfe. 5. The eye needs to be inspected much sooner, certainly by the end of the third day. And even if these or similar rules be followed, Derby cannot resist the belief that for the average surgeon, and in the present state of our knowledge, simple extraction at the best involves an element of danger that is wanting in the method of Gräfe. The successful extraction without iridectomy is unquestionably the more brilliant of the two methods, and the patient thus cured a more striking exemplification of surgical skill. A greater familiarity with the new operation may cause the risk to assume inconsiderable proportions. But some risk is likely always to remain. It is like the old question as to the relative advantages of ether and chloroform: the latter easier to transport, pleasanter to take, quicker in its effect, and occasionally alarming in its consequences.

The Spirit of the Societies.

SOUTH AUSTRALIAN BRANCH OF THE BRITISH MEDICAL ASSOCIATION, January 26th, 1888. Total Extirpation of Larynx.—DR. GARNER read the notes of a successful case of total extirpation of the larynx, performed by him for cancer. He also showed a vulcanite artificial larynx, made by Dr. Woodburn, especially for him, at Dr. Newman's request. It had been modelled after Foulis' original instrument. The ordinary silver instrument looked alarmingly big and heavy in comparison.

DR. DAVIES THOMAS raised the point as to whether the operation could be called a justifiable one. Personally he knew nothing about the matter, but he thought it was a matter of importance to the profession to consider the ground on which it would be judged by the outside public. He thought that as regards English surgeons there was a consensus of opinion against it—a feeling that the average result was not sufficiently good. He would refer to Dr. Morell Mackenzie's book on the subject. The great question was did it sufficiently prolong life to make it worth while running the great risks incurred. That should be the basis on which it should be judged. As an example he would refer to Keith's remarks on the justifiability of operating for fibromata of the uterus. Just before leaving London, two years ago, his friend, Dr. Felix Semon, had a German surgeon to operate on Mr. Montague Williams, removing a portion of the larynx. At the same time Dr. Semon had strongly expressed his opinion that as a rule he did not consider the operation a justifiable one. Dr. Thomas regretted that he did not remember what had been the circumstances making it justifiable in Mr. Williams' case.

DR. GARDNER, in reply, said that nothing would have pleased him better than to have been able to answer Mr. Hayward's queries. He said that was just what they had yet to find out. He did not set himself up as an authority on the operation, as he did not consider that he had had yet sufficient special experience. Taking all the cases on record, they did not yet exceed one hundred. Hahn, of Berlin, had operated upon fifteen cases, nine in which the larynx was partially removed, and six in

which there was total extirpation. One of these latter had made a complete recovery, and had survived the operation, as yet, seven years. If, therefore, even one in fifteen had no recurrence of the disease, surely that was enough to justify the operation. In judging of the opinion of English surgeons, great stress must be laid on the miserable, foggy, damp climate of England. In Great Britain there had only been as yet two successful cases of complete laryngotomy, all the others had been failures. And these two cases had been operated on in Scotland. It was very natural, therefore, that there should be felt a certain amount of disinclination on the part of English surgeons to attempt it. He thought the profession was not yet in a position to decide either for or against it. What he would recommend was, that surgeons should go on working, and, after a time, the necessary data would be forthcoming. As regards the operation itself there was nothing very formidable about it, if only the operator had familiarised himself with it before-hand, by operating on the cadaver. He must acknowledge that his first case was rather disappointing in its results; but then it was a very unfavourable subject, as the disease had already lasted two years. If the prolongation of life should be found to be only ten months duration, the operation would certainly not be justifiable. He hoped however, for better things.

[*Statistics.*—The *British Medical Journal*, April 7th, 1888, gives the following: "The disastrous results of several cases in which similar operations have recently been performed seem to have opened men's eyes to the magnitude of the risk to which the Imperial patient would have been exposed but for the intervention of the English physician, in whom he not unnaturally places such confidence. Thus, our Berlin correspondent, who is in a position to know facts, informs us that Herr Kayser, a prominent member of the Social Democratic party in the German Reichstag, died a few days ago, immediately after half of his larynx had been cut out, by Professor Von Bergmann, for cancer. We are also informed that all the eleven other patients on whom that distinguished surgeon has performed this severe operation have since died. Dr. Eugen Hahn, who has hitherto been the most successful operator in that line, has been equally unfortunate in his last two cases. Only the other day an operation of the same kind, performed by a leading London surgeon, resulted in the death of the patient on the third day. In private one hears of many cases which have not yet come publicly before the profession."]

MIDLAND MEDICAL SOCIETY, March 27th, 1888. **Acute Peritonitis treated by Abdominal Section.**—Mr. LAWSON TAIT read a paper on a series of cases of acute peritonitis treated by abdominal section. The cases supported the growing opinion that acute peritonitis is usually of local origin, and also that if operation is to be done successfully it must be performed early. One case illustrates the danger of puncturing through the rectum, ovarian cysts obstructing descent of the foetal head. Mr. Tait said that suppuration always followed such methods of puncture. He quoted a case to show that gonorrhœa, acquired before or during pregnancy, might give rise to acute peritonitis, and gave it as his opinion that such condition frequently occurred. Another case where acute peritonitis had resulted from the suppuration and bursting of a hydatid cyst, and which was treated successfully by abdominal incision and drainage. Another case, where peritonitis had followed gall-stone colic, also treated successfully. Another, where no local cause could be found; and another where tubal disease had given rise to the peritonitis. He had operated on eight acute cases during the past seven months, with six recoveries. One death was due to delay in operating, and the other occurred in a primiparous woman—a class who are not only more liable to this disease, but in whom also it runs a more rapid and a more fatal course. The abdomen should be opened through a small incision between the pubes and the umbilicus; any local cause which can be found should be dealt with. The cavity should be thoroughly washed out with plain warm water, and drained until free exudation has ceased.—There was a good discussion, in which Drs. Bennett, May, Macan (Dublin), Lloyd, Johnston, Taylor, and Donovan took part.

Medical Miscellanea.

THE subject of our next illustration will be Hugh Owen Thomas, Esq., Liverpool.

Contagious pneumonia, swine plague, or hog cholera has been very prevalent in the neighbourhood of Marseilles; 30,000 hogs have died.

Sir Prescott Hewett and Sir Thomas Longmore have been elected foreign associates of the Academy of Medicine, Paris.

The next International Congress of Chemists and Pharmacists will take place at Milan next September.

There are 102 lady students attending courses of medicine in Switzerland.

Mr. Robert W. Doyne has devised a new Stereoscope for the purpose of thoroughly carrying out orthoptic training of the eyes.

The Academy of Medicine, Paris, has pronounced unfavourably on M. Luy's experiments on hypnotic subjects.

Sir James Paget will preside, on May 2nd, at the dinner of the Royal Literary Fund.

We have received the first number of the "Nursing Record," a journal for nurses and chronicle of hospital news. We wish the new venture all success.

The Seventeenth Session of the French Association for the Advancement of Science took place at Oran, commencing 29th March. Medicine forms a very important section in this association.

An Otological Congress will be held at Bruxelles from 10th to 15th September. Dr. C. Garis, Rue Royale, 143, Bruxelles, will receive all announcements and give any information.

Dr. William Sinclair, M.A., M.D., C.M., Hon. Physician to the Manchester Southern Hospital for Diseases of Women and Children, has been appointed Professor of Midwifery to the Owen's College in the place of Dr. Cullingworth.

We regret to announce the death of William Alexander, M.D., F.R.C.P. Lond., on April 13th, at the age of eighty-two years. His family have been settled in Halifax for a century and a half, and he had been in practice in Halifax for nearly half a century. He was connected with most of the local institutions, besides being a J.P. for the county.

If M. Gautier's observations be correct, the bodies of all dogs destroyed from, or on suspicion of rabies, should be cremated. M. Gautier states that the medulla of a dog dead from rabies, removed seventeen days after death, then buried in the earth for fifteen days longer, preserved all its virulence. Inoculations from it caused rabies in twelve days.

A SCENE FROM LIFE.—Earnest Scotch student with his ear on the stethoscope: "Now, my man, draw a long breath." Patient: "Och, thin, if you don't lane lighter you won't let me draw a breath at all." Remarks afterwards: "Me to draw a long breath, with twelve stone weight on me ribs."

Dr. John M. Browne has been nominated Surgeon-General of the United States Navy. He was Surgeon to the Kearsage during the memorable fight at the Alabama. He was a delegate from the Medical Department of the Navy at the International Medical Congresses of London and Copenhagen.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "The Provincial Medical Journal," Horton House, Halifax.

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester; or to the London Representative, Mr. E. BELLA, 58, Charing Cross Road, W.C., to whom all communications respecting Advertisements should be addressed.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked. Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

IMPURITY.

To the Editor of "The Provincial Medical Journal."

SIR,—I wish to present some considerations relative to the great question of purity which you have raised in one of your leaders this month. For many years I had medical charge of a district in the centre of Ireland, with an agricultural population of about 3000. Illegitimacy was very rare, and for years I never saw a case of specific disease. I made inquiries as to whether patients so affected could be going any where else, and I found there was no evidence that this took place. I believe that this immunity from specific disease is the rule among the agricultural population in Ireland. In my opinion, this state of things is due to two causes: One is that the people, male and female, have been thoroughly instructed by their religious teachers that impurity is wrong; the other is that the practice of early marriage takes away the temptation to impurity. In England a great number of the people are very little removed from the beasts in their notions of morality; and, in cities especially, the hindrances to marriage are very great. There is truth in the remark I lately read: that both idleness and overwork are fruitful causes of immorality. Both these causes are powerfully at work in England. A majority of the population are working like galley-slaves to keep a minority in idleness. All past history shows that whenever a nation has become, in its aristocracy, idle and dissolute, and in its democracy, drunken, over-worked, and sensual, dissolution is near at hand. The hope of England lies in the enlightenment of its democracy. Instruct and elevate the people, and, along with that, restore to them the land which is rightfully theirs. If this be done speedily, it will stop the rush to the cities. Men will then build houses and live in them, and marry and give in marriage. If this is not done in a legal way, it is very certain that ere long society will be overturned to its foundations.—Yours, etc.,

VOX.

Belfast, April 10th, 1888.

TURKISH BATH IN A PRIVATE HOUSE.

To the Editor of "The Provincial Medical Journal."

DEAR SIR,—I shall feel greatly obliged if any of your readers will let me know if there is any work published, and if so the publisher of it, giving plain directions how to erect and manage a Turkish Bath in connection with a private house.—Faithfully yours, M.D.

April 16th, 1888.

THE "PYRETIC" ACTION OF ANTIPYRIN.

To the Editor of "The Provincial Medical Journal."

SIR,—A microscopic examination of the effects of a solution of antipyrin upon the blood convinced me some time ago that the drug is an antipyretic, solely in virtue of its power in preventing the formation of fibrin. By fluidising the blood it consequently diminishes the resistance to its current, and obviates *stasis*. This relieves tension, and reduces cardiac excitement and action accordingly. The result is a corresponding reduction of temperature. But the same power of preventing *stasis* of the blood may be taken advantage of in treating the *stasis* of syncope. There is stagnation in the capillary system, and laboured action of the heart. Antipyrin, by fluidising the stagnating blood, relieves the heart and re-establishes the blood-current. It is thus a powerful restorative in such cases. It may be given in the form of a draught of fifteen or twenty grains, with ammonia, or brandy, or wine, or by intravenous or hypodermic injection with ether. In the same way it is useful in the congenital debility, with feeble circulation, of infants, given in grain doses, with a little borate of soda, three or four times a day. If these observations have any foundation in fact, a better name for the drug would be *antistasin* or antifibrin. Confirmation or complete refutation of them could easily be furnished by direct experiment upon the lower animals. It would be found that after full doses of the drug the blood of the animal would be devoid of clotting power on being shed. If confirmed, a guide would be furnished for the indications and contra-indications in the prescription of this potent drug. It would be proved that there is grave danger in the giving of it to those who suffer from diseases associated with a diminution of fibrin, such as all septicæmic affections, typhoid conditions, puerperal fevers, *et hoc genus omne*.—I am, Sir, yours faithfully,

April 19th, 1888.

C. R. ILLINGWORTH, M.D., M.R.C.S.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

- Transactions of the Obstetrical Society of London. Vol. xxix., year 1887. London: Longmans, Green & Co.
- Transactions of the Academy of Medicine in Ireland. Vol. v. Edited by William Thompson, M.A., F.R.C.S. Dublin: Fannin & Co.
- On Gonorrhœal Infection in Women. By William Joseph Sinclair, M.A., M.D. London: H. K. Lewis.
- Second and Third Reports of the New York Cancer Hospital.
- The Lettsomian Lectures—On Some Points in the Surgery of the Urinary Organs. By Reginald Harrison, F.R.C.S. London: J. & A. Churchill.
- Outlines of Qualitative Analysis. By George W. Slatter, A.R.C.S. London; Thomas Murby, 3, Ludgate Circus Buildings.

Our Portrait Gallery.

HUGH OWEN THOMAS.

It is now a hundred years ago since Park, a Liverpool surgeon, ably advocated excision as an alternative to amputation, and became a pioneer in a crusade which resulted in great benefit to mankind. It is a strange coincidence that the writings of another Liverpool surgeon, Mr. H. O. Thomas, have been mainly instrumental in rendering infrequent an operation which a century back was an unmixed good. And yet at both periods the reforms were needed in the interests of that conservatism which alone merits the name of surgical advance.

The subject of our sketch was born in Anglesea, North Wales, August 23rd, 1834, and having undergone the usual preliminary training of early life, became in 1850 an articled pupil to his uncle, the late Dr. Owen Roberts, of St. Asaph. He always refers in kindly terms to this apprenticeship, and to the advantages he derived from association with so cultured an intellect, and so experienced an instructor. After a sojourn at Edinburgh and London, he was admitted a Member of the Royal College of Surgeons in 1857. He soon afterwards started practice as a general practitioner, and in a short time became encompassed with work. In 1873 he published his first pamphlet, the subject being the treatment of compound fractures of the lower jaw. He advocated with certain reservations drilling the maxillary bone, wiring, and so arranging the twist coil as to readily admit of tightening, or the reverse. Two years later he published the first edition of his volume, entitled "The Treatment of Diseases of the Hip, Knee, and Ankle Joints," which is now so generally known, and in this volume were first figured the splints for the hip and knee, which are called "Thomas's Splints." In the inventor's splint room may be seen models illustrating the slow evolution which these splints have undergone before arriving at their present stage. Mr. Thomas, however, has always looked upon them as very secondary to a correct appreciation of the principles which he lays down as governing

the successful treatment of diseased articulations. Closely following this work there appeared the volume, which he considers his best, entitled "The Treatment of Intestinal Obstruction," wherein he advocated, in contradistinction to the tendencies of the teaching of the time, a reduction of bowel contents. This has been followed by many other volumes, amongst which we may mention that on "Inhibition of the Nerves," which aimed at rationalizing the art of prescribing; "The Collegian of 1666 and the Collegians of 1885;" a polemical brochure justifying the publication of his intestinal work, and extolling the principles advocated by Sydenham when compared with those of modern physicians. Later he has published "The Principles of Treatment of Joint Disease," "The Principles of the Treatment of Fractures and Dislocations," and "Injuries and Diseases of the Trunk and Upper Extremity." Among his minor contributions we may name "Fractures of the Patella," "Fractures of the Neck of the Femur," "A Review of the Past and Present Treatment of Joint Diseases," and only lately in our columns a description of a new Lithotomy operation.

Having started his professional career as a general practitioner, he has never been able to favour specialism, and in every surgical or medical undertaking he is governed by general principles which in certain features are identical. This generalization is only possible when a large and diverse field of work is submitted to observation. If we were to attempt to analyse Mr. Thomas's special aptitudes, we should say they consisted in an original mind not in the least tainted with reverence for authority as authority, whatever its source.

For thirty-one years he has not had a single day's holiday, and when not engaged at literary work he spends his evening with his lathes. Work is his only enjoyment, if we except cigarette smoking, and the text which he has chosen as a motto to one of his pamphlets accurately describes the man. It runs:—"Wherefore I perceive that there is nothing better than that a man should rejoice in his own works; for that is his portion; for who shall bring him to see what shall be after him."

Original Communications.

THE TREATMENT OF UTERINE DISPLACEMENTS.¹

By HENRY R. HATHERLY, M.R.C.S.,

SURGEON TO THE HOSPITAL FOR WOMEN, NOTTINGHAM.

SO MUCH has already been written and said on the subject I propose to introduce for discussion to-night, that it may seem somewhat presumptuous in me to express my own views on that which has already occupied the attention of so many distinguished gynaecologists. My excuse is that there is such a total want of agreement amongst the many authorities who have made known their views, that the whole subject of the treatment of uterine displacements may still be considered *sub judice*. The very variety of pessaries which have been from time to time introduced for the treatment of uterine displacement, most of which are praised by some and condemned by others, is evidence that there is no common ground of agreement, even on the purely mechanical treatment of some of the commonest diseases of women.

I do not propose to waste your time by describing in detail the various kinds of displacement which are described in all text-books, and with which you are as familiar as I am; and, as I fully agree with Mr. Lawson Tait when he asserts, that he can find no more complete and satisfactory account of uterine displacements than that given in the Clinical Lectures of Sir T. Y. Simpson, I shall adhere to his nomenclature. Thus, by version, I mean that the uterus is turned out of its proper axis without being bent; and, by flexion, I mean that the womb is bent with a more or less sharp curvature; by procidentia I mean incomplete descent of the uterus, and by prolapsus complete descent; the difference being one of degree rather than of kind, it is difficult to define where one begins and the other ends, and any distinction must be arbitrary. For practical purposes I should draw the line at the extrusion through the vulva of any portion of the organ.

As the causation of uterine displacement is a very important indication for its rational treatment, I must ask you to bear with me whilst I glance very briefly at some of those conditions which have a tendency to bring about either version, flexion, or procidentia. It is not often that a displacement can be referred to any one cause, but usually several causes contribute to produce the result. Few will doubt the important part that childbirth plays in the production of displacements, yet childbirth is a natural physiological process, and ought not under normal conditions to be followed by any evil consequences. Displacements due to childbirth alone may usually be prevented, and are perhaps the most readily curable. But how often do we find normal conditions wanting in the pregnant woman? We shall find, in addition to the accidental cause of parturition, one or many amongst the following predisposing or contributory causes—viz., enfeebled general health with a relaxed muscular fibre, the bad habit so many women acquire of habitual constipation, retention of urine for prolonged periods, insufficient rest in horizontal posture, lifting or straining too soon after confinement, especially where there is deferred

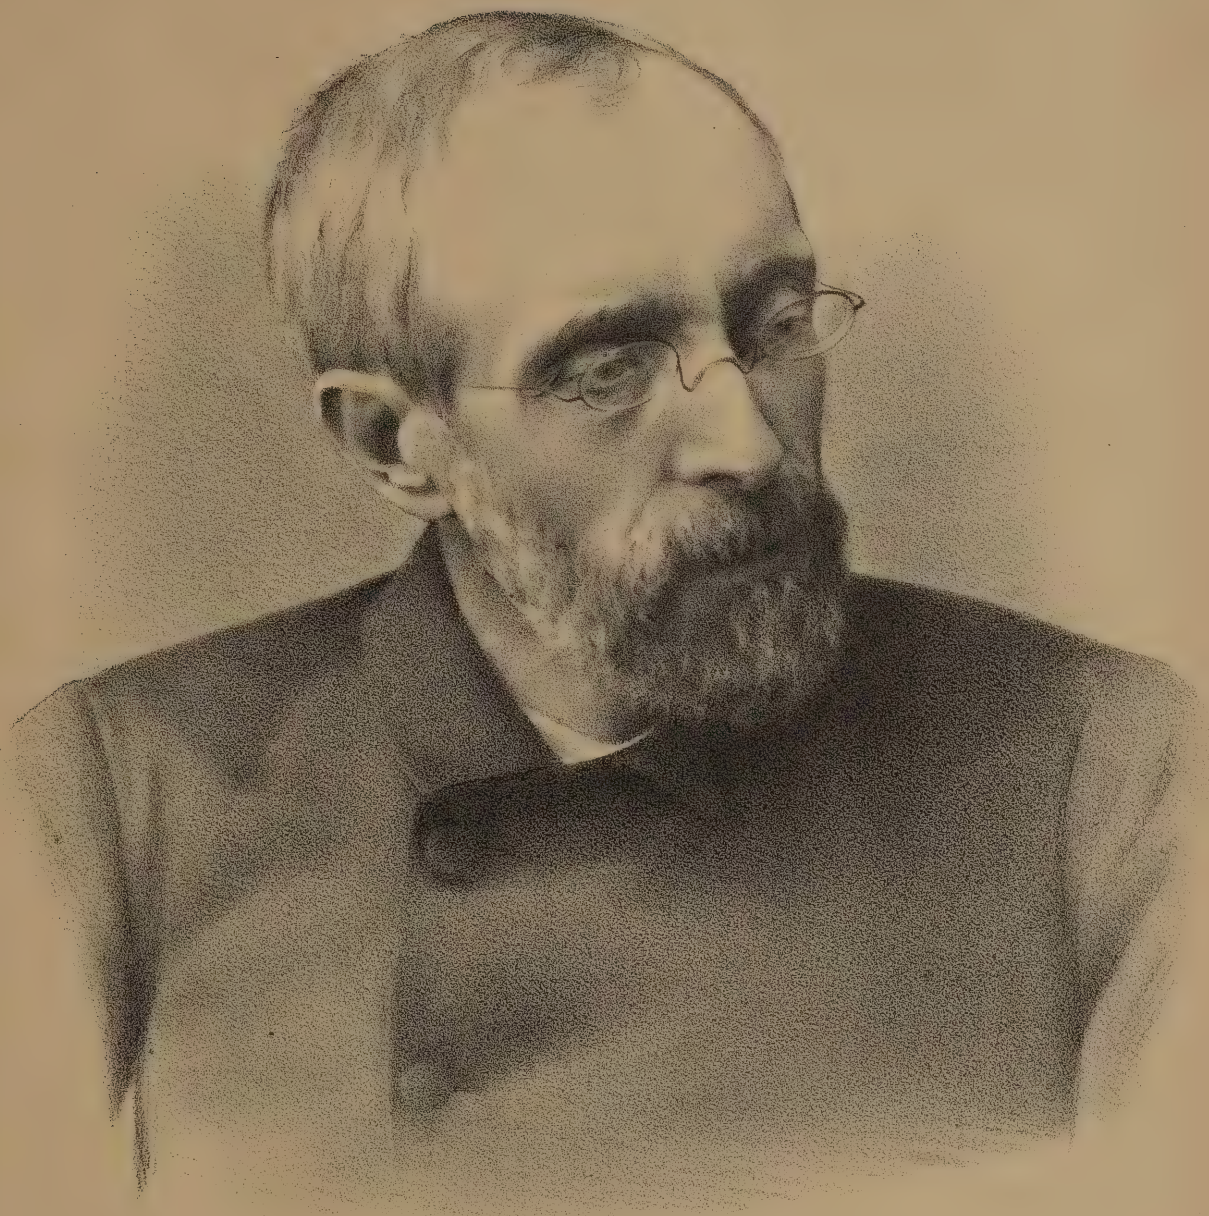

involution of the womb, tight clothing, chronic cough, and a variety of diseased conditions it is needless to enumerate.

Whatever the cause or causes of uterine displacement, they may be divided into two classes: temporary and permanent. The former being preventible and generally curable, the latter being far less amenable to treatment. If the uterus is only displaced by its own weight, and a relaxed condition of its normal supports, and contributory causes are of such a nature as to be removed, then much may be hoped for from a rational treatment, mechanical or otherwise, adapted to the special circumstances of each case. If, on the other hand, we find some more or less permanent mechanical causes of displacement, if the uterus is displaced by the product of disease, such as tumours, inflammatory exudations, hypertrophy of neighbouring organs, etc., we have little to hope for from mechanical treatment, and must direct our attention chiefly to the treatment of the permanent cause rather than to the mechanical effects. As a broad general principle, we may judge of the temporary or more or less permanent character of the cause by the mobility or immobility of the uterus. Whatever its position, if we find that it cannot be altered by bi-manual efforts, or by the sound, (although I am strongly of opinion that the sound can rarely succeed when bi-manual efforts have failed,) then I think it is a safe conclusion that any kind of pessary, however carefully adjusted, will be not only useless but mischievous. I do not propose to discuss immovable displacement, but will confine my attention solely to that class of case in which the uterus can be replaced in its normal position by assuming the horizontal position, or by gentle manipulation.

If we admit that a slight degree of anteversion is the normal condition of the uterus, by far the commonest displacement is that which women generally describe as "a bearing down," and which we term procidentia; and this condition is, unhappily for the sufferers, often allowed to proceed from bad to worse, until such a serious degree of discomfort and inconvenience arises, that as a last resource a doctor is consulted. In such cases we commonly find that the horizontal position is almost sufficient to effect a replacement of the organ, and, if the disease be not too far advanced, may suffice without other treatment to effect a cure. This will be more particularly found to be true in such cases as have been mainly caused by deferred involution, relaxed condition of vaginal walls, and of uterine ligaments, and any kind of debility which yields to a tonic plan of treatment. But we meet with a large number of cases in which the uterus, however easily replaced, at once returns to its abnormal position, unless retained by mechanical means, and in which prolonged and absolute rest, however desirable, is impracticable, in such cases a carefully selected and well adjusted pessary will often prove our best resource.

Some writers express doubt as to the curability of uterine displacement, and I think if pessaries alone are to be relied on they are very nearly right. I believe that many patients however may be permanently cured by prolonged and absolute rest, if they can only be induced to submit to it. Therein lies the difficulty. The slighter and more curable displacements are not usually productive of acute pain; there is a sense of weight and uneasiness, relieved by rest, and exaggerated by fatigue or exertion, and that seems to most women an insufficient degree of suffering to necessitate complete rest. They find that a pessary retains the uterus *in situ*, without causing pain or discomfort after a very

¹ Read before the Nottingham Medico-Chirurgical Society, April 6th, 1888.

Yours Very truly
A. H. Thomas

short time, and they rest satisfied with palliative measures, because curative treatment would interfere with household and maternal duties. A few years ago I attended a lady who had married young, and who had been confined three times, the intervals between her pregnancies being very short; she was of an active temperament, and had been governed by the "ninth day" superstition, not getting up before that had elapsed, but very soon after. When I first saw her she was pregnant for the fourth time, and she complained of much bearing down. I found that a former medical attendant had inserted a ring pessary for a well-marked procidentia. The pessary, although limiting the descent of the womb, did not restore it to its normal position, and caused considerable irritation and discomfort. On examining her in the erect position, the gravid uterus was low down pressing on the perineum, the os uteri could be felt just within the sphincter vaginae, but on lying down the womb fell back almost to its normal position. I advised her that if she would only consent to keep her bed for at least a month after her confinement, she would be very likely cured of the bearing down permanently, but warned her that if she got about too soon the tendency of the disease would be to get worse rather than better. She agreed to do as I advised, and the result fully justified my anticipation, as she has not suffered since, although she has had additions to her family. I quote this case as a typical, although commonplace instance, of the more curable forms of displacement. It would be interesting to obtain the history of some of those women who, suffering from procidentia, have been compelled either by surgical injuries or disease to involuntarily submit to prolonged rest. Such cases must be far from uncommon, although I have failed to meet with any records of them. I attach great importance to general and constitutional treatment of procidentia, but after all, in the great majority of cases, we are forced to add purely mechanical treatment by means of pessaries.

The pessaries generally used for procidentia are the ring, the spherical or egg shaped vulcanite ball, a Gariel's air, all of which derive their support from pressure on the vaginal wall, and pessaries of which Barnes' and Napier's are types, deriving their support from a stem which is maintained in position by bands and belt. The former are the more comfortable, but the latter more likely to produce permanent good effects. Any pessary which is supported by pressure on the vaginal walls cannot be curative; in fact the distention of the vagina must tend to its shortening, and so the uterus is slightly dragged down. There is another defect in all intra-vaginal pessaries, and that is by dilating the vagina they often require to be replaced by larger sizes. The ring pessary is perhaps on the whole the most generally useful, and does not require very much attention. I need not relate those precautions which may be found in every text-book. The egg shaped or spherical vulcanite or box wood pessary is a useful one for those patients who are perhaps only able to be seen at long intervals; it can be easily cleansed and replaced by the patient herself, and the pressure on the vaginal walls is much more evenly distributed than is the case with ring pessaries. I have in my own practice discarded almost every other pessary in the treatment of simple procidentia. My experience is that few women will submit to the almost invariable discomfort caused by those pessaries which are supported from without; the tapes or india rubber bands get wet and soiled, the skin gets chafed, and although on theoretical grounds I should prefer them, I find they can seldom be worn long enough to do any lasting good. In

very extreme cases, after the climacteric period, Sims' or Emmet's operation will often prove beneficial, or the shortening of the round ligaments as practised by Alexander. My colleague, Dr. C. V. Taylor, has performed Schroeder's operation two or three times with excellent immediate results, and I shall not hesitate to treat suitable cases when they occur in that manner. The repair of a ruptured perineum is so obviously a necessary preliminary to other treatment, that I need only mention it.

Until 1773 we have no records which prove that either flexions or versions of the uterus were recognised, but in that year Levret, a Frenchman, described anteversion as a displacement of the uterus, of which authors had not hitherto spoken, and Dr. William Hunter appears to have been the first to describe retroversions some years later. Since that time great advances have been made in our means of diagnosis and of treatment. It is a question not to be answered hastily whether the increased attention which has been paid to uterine displacements, and the facility with which they may now be diagnosed, has not on the whole proved rather a curse than a blessing to suffering female humanity. Scanzoni lays down as a law "that flexions of the uterus are never of much importance except when some other affection of the uterine substance is associated with them," and I think the tendency of modern opinion is leaning more and more towards the rule laid down by this old writer. Flexions have been recognised and treated as such, endless pessaries have been devised, and in some cases may have done good. There can be little doubt that many cases will improve whilst a patient is wearing a pessary, and no doubt the whole credit of any improvement is attributed to the pessary, but often the relation of cause and effect is assumed without much reference to other factors acting simultaneously.

It is generally admitted that slight anteversion is a normal condition, and that even very marked anteversion will often exist without causing any symptoms; the patient is quite happy and contented until some other cause leads to an examination, and then too often the anteversion receives all the attention, which should more properly be directed to the additional circumstances which first directed attention to it. If we assume anteversion to be in itself a diseased condition, it is one which *per se* needs no treatment unless severe mechanical dysmenorrhœa accompanies it, and can be accounted for on no other hypothesis than that it is caused by the deformity. Thus the treatment of anteversion resolves itself practically into the treatment of any accompanying condition, which either aggravate or are aggravated by the flexion. I question seriously whether any kind of vaginal pessary, however ingenious, has the slightest influence on anteversion; when they seem to do good it is by remedying some attendant procidentia. The only kind of pessary which can be proved to straighten the flexion are stem pessaries, which require very great care, and are not devoid of danger. When stem pessaries in the hands of some gynæcologists are believed to be of great value, the beneficial results obtained are not improbably due to other points of treatment, which are carried on simultaneously—rest, attention to general health, the state of the secretions, etc.

Anteversion is not in my experience a very common condition of a healthy womb. Women with flabby abdominal muscles and pendulous abdomen are the most likely subjects for this form of displacement, as a sequel to congestion or sub-involution after childbirth. If the womb is weighted by a fibroid, bound down by inflam-

matory adhesions, or pressed upon by abdominal tumours or hypertrophy of any neighbouring organs, or is the subject of malignant or other disease, anteversion is not likely to be remedied by mechanical means, and it is beyond the scope of my intention to refer to the treatment of permanent causes of displacement. Probably Kiswisch was correct when he accounted for the greater frequency of posterior displacement by the fact, that whereas the accumulation of urine in the bladder takes place from below upwards, that of feces in the rectum is from above downwards, and that natural mechanical causes favour retroversion rather than anteversion. If the uterus is movable, and can be replaced by bi-manual efforts, or even by the sound, a less desirable method, then treatment may be in many cases very successful. When rest can be enforced, the horizontal position, with the head of the bed rather lower than the foot, should form an essential part of the treatment, congestion if present must be treated by local and constitutional means. A bandage or abdominal belt is a useful adjunct, provided that the pressure may be greatest at its lowest circumference. If laced, the lacing should always be from below upwards. I cannot say that I have any great faith in any of the numerous pessaries which have been devised for the treatment of anteversion. If there is any local congestion or inflammation, pessaries would only serve to increase it. Sometimes the use of tampons, as applied by Dr. Marion Sims, may be well borne when pessaries are contra-indicated. If anteversion exists without any accompanying procidentia, pessaries may in my opinion generally be excluded from any system of treatment adopted.

Posterior displacements are much more commonly met with than anterior ones. One cause is over-distension of the bladder; and a brief consideration of the relations existing between the uterus and the bladder at once explains the *modus operandi*. Also Douglas's pouch forms a very convenient receptacle for the fundus of the uterus when retroverted or retroflexed. The Hodge pessary, so invaluable in retroversion, is less generally serviceable in retroflexion, the upper bar resting in the concavity of the flexion, a large flaccid uterus may easily roll over the top of the pessary, in which case no relief will be obtained.

The reflexed uterus may generally be easily replaced by manipulation or the sound, only to fall back again when the finger or sound is withdrawn. In such a case we have two alternatives: the insertion of a stem pessary, or packing the posterior vaginal fornix with tampons. I think that stem pessaries should only be resorted to in extreme cases, after other less dangerous methods have been exhausted.

The treatment of retroversion is much more satisfactory than that of either retroflexion or anterior displacement, but considerable care and judgment is required to select from amongst the many modifications of the lever pessary one which is exactly adapted to any particular case. I prefer in most cases a simple vulcanite pessary; the size must be carefully attended to, as too small a one will slip, and too large a one will produce unnecessary discomfort in the wearing, as well as pain during its introduction. Having replaced the uterus, and adjusted the pessary, it is desirable in out-patient practice to let the patient remain for a short time, walking, standing, and sitting down, as the relief afforded by a well-adjusted pessary is immediate. The surgeon, by adopting this plan, at once tests the value and suitability of the mechanical appliance. If no sensible relief is afforded, and still more if any pain ensues, it will

be useless to allow the pessary to remain, as it is almost certain to do harm. The great advantage of the lever pessary is that it is not retained *in situ* by distension of the vaginal walls; thus it can be worn for long periods if occasionally cleansed and replaced, without causing soreness or irritation. I do not feel at all sure that the best adjusted Hodge pessary is ever in itself curative, I should rather say it is like the crutch to the lame man, of immense use whilst nature is doing her work, affording a useful support to a weak part, and nothing more. I look upon a pessary as a mechanical contrivance which, except in incurable procidentia or prolapsus, should be only considered as a temporary adjunct to other treatment; it has however, no doubt by some practitioners been much abused. I have come across patients who have worn pessaries for ulceration of cervix, for hypertrophy of the cervix, or for uterine tumours, or for a mere sense of bearing down in which no displacement of the organ existed.

Pessaries are contra-indicated—1. In recent displacements due to sub-involution of the uterus after confinement. 1. When the uterus is fixed and immovable, whatever its position. 3. Whenever they cause actual pain. 4. During pregnancy. 5. Whenever they fail to retain the replaced uterus to some extent in its normal position; for example, if an antelexion continues, a pessary notwithstanding, the pessary is useless. The rules which have hitherto guided me in the use of pessaries are few and simple—1. To replace the uterus as a necessary preliminary. 2. To select the smallest sized pessary which is capable of fulfilling the desired object. 3. Only to continue their use when an increased sense of comfort is the result. 4. To remove them from time to time, that they may be cleansed, and any improvement may be noted. 5. To discontinue their use at the earliest time which is practicable. 6. Whenever there is a reasonable hope of cure, to avoid any kind of pessary which is retained *in situ* by distension of the vaginal walls.

In conclusion, the treatment of the various displacements of the womb, must, to be successful, be general and constitutional as well as mechanical. Too much importance should not be attached to the mere fact of displacement, unless it is productive of clearly defined symptoms which cannot be legitimately attributed to other causes. Slight deviations from the normal position do not need any special treatment, although it may be very desirable to lay down certain precautions for the guidance of the patient. An indiscriminate resort to pessaries in every form of displacement cannot be too strongly deprecated, for their injudicious use often perpetuates the evil they are intended to remedy.

A FEW COMMON ERRORS IN THE TREATMENT OF FRACTURE.¹

BY ROBERT JONES,

SURGEON TO THE LIVERPOOL STANLEY HOSPITAL.

IF we wish to succeed in the treatment of fractures, we have to regard at least three points. The first is that fixation should be efficient and sufficiently long continued. The second, that apposition be good, and the third, that the circulation of the limb be not unduly hampered. Elementary as these canons appear to be, most failures can be traced to disregard of them, and this not because of scepticism concerning their importance, but by reason of defective knowledge of the means to attain desired ends.

¹ Read at the North Wales Branch Meeting at Colwyn Bay.

If we wish fixation to be efficient, we must see that leverage is not deficient. We must not treat the surgical neck of the humerus by an inside splint reaching only so high as the axilla. Nor should any theories we may hold concerning stiff wrists prevent our remedy for Colles's fracture from extending to the knuckles; nor should fractures of the upper third of the ulna and radius be treated without locking the elbow joint; nor for similar reasons should the knee be left free when the upper portion of the tibia has been severed.

To secure efficient fixation we should employ splints with sufficient concavity to permit of their slightly overlapping limbs. By this precaution we avoid that constant twisting which characterizes the movements of limbs confined in the old-fashioned plane splints. In relation to circulation we should bear in mind that any interference with the blood supply to the fractured ends materially retards the curative results, and for this reason we should avoid tight bandaging. Many cases of non-union are due to this error. A badly set fracture generally gives rise to no worse complication than deformity, but tight bandaging may be guilty of any crime between simple discomfort and gangrene. Most frequently, however, delayed-union is the evil result which must be laid at its door. On several occasions I have been shown cases which have far exceeded the normal period of treatment where the fractures have apparently made no effort at repair. Success is generally assured in such, provided free circulation be encouraged and local stimulation applied by means of fist or hammer. Gentlemen will bear me out when I say that in nearly all cases of ununited fractures, say of the femur, patients will unroll yards of bandage, which leave marked depressions behind, and which strongly suggest the continuance of an initial error.

The same results occur if splints are chosen which are not sufficiently wide. It is always better in cases of fracture to apply splints wide enough to admit of a space between the bandage and flesh. Under the bridge so formed the blood supply to the limb is unhindered, and there is little or no danger of any congestive disturbances. Again, in this connexion, we have many errors in the distribution of pads. There is a danger of so placing them, that although apart from each other, they would if approximated form a ring around the limb. The mechanical power of the pad is almost unlimited, and it requires, therefore, much care that error be excluded in its application. Pads should never be applied over large blood-vessels.

A very common mistake consists in carrying the splints for fractured forearms or legs too high. This is very easily overlooked, and should be remembered. In setting a forearm it is well to flex the elbow, and so make sure that the top of the splint does not press into the bend of the elbow. The same principle holds good in the case of the popliteal space. I have committed both these blunders, and the patients rarely forgot to indicate their contempt for my mechanical *acumen*.

Doubtless it is very important to attain good apposition, but with the exception of fractures of the lower end of the fibula and radius, it is not important to attain immediate reduction of deformity. It is one thing to strive for immediate symmetry of limb, another to aim at putting the bones in absolute line. No matter how great the swelling or painful the limb, it should not be allowed to remain crooked, and any bone pressing on the skin should at once be replaced. Neglect of this precaution may result seriously, either in relation to the vitality of the limb, or in transforming into a compound that which

should have remained a simple fracture. A careful adjustment of pads will rectify without any difficulty any bone irregularity during the first fortnight, and with special methods will correct misplacements much later. Great care is necessary from the point of view of apposition in the choice of splints, and without going into details I would condemn the routine use of plaster-of-Paris and of Gooch splints. The former if put on at once, as is now a growing custom, becomes slack as soon as the swelling has subsided, and admits of motion. It practically does away with the intelligent use of pads. It does not allow harmless inspection, and, therefore, what should have been corrected becomes confirmed. If put on when the swelling has disappeared, it is still a form of circular compression, which tends to interfere with the vitality of the limb, and often delays union. When placed round the thigh in fracture about the fifth week, to allow of walking, its action is very pernicious. A thigh of normal length may be indefinitely shortened, as the support merely represents a casing sufficiently loose to allow of a telescopic action of the leg within it. The drawback in principle of the Gooch splint, now so generally used, should be very apparent. For example, consider its bearings in fracture of the radius: it will not yield lengthwise, but laterally it will to any extent, the result being that it may press the fractured ends of the radius on to the ulna, if the bandaging is sufficiently stern. In fact, the splint depends largely upon the bandage for the shape it takes—a defect surely sufficiently grave.

Unless very carefully superintended, pads should not be placed on thinly-clad bones, otherwise a slough will result. Twelve hours should be the outside limit allowed it to remain. Then, whether a complaint be made or not, the spot should be inspected. Over and over again I have told house-surgeons not to mind the patient's sensations, but to feel convinced that after a certain pressure a slough may be expected. To the astonishment of some who have neglected my advice, they have discovered a black slough, although the patient has been in absolute comfort. If therefore it becomes imperative to employ pads in such positions, we should remember to change frequently, and at stated intervals, regardless of the patient's feeling or comfort. Perhaps the most serious error in the treatment of fractures is the two early casting off of restraint. This in the case of pauper patients is unfortunately more or less inevitable, because of the coercive tendencies of hospital committees, but in the well-to-do classes some rule should govern our conduct. Over and over again we read of cases sent out with normal limbs, coming back two months later with two and three inches shortening. Here it will be of interest perhaps if I state the time I am in the habit of keeping patients under restraint for various fractures.

	Total Restraint.	With further Partial Restraint.
Femur	8 weeks	3 months
Tibia and fib.	5 weeks	2 months
Fibula	4 weeks	2 months
Potts	4 weeks	1 month
Humerus	6 weeks	6 weeks
Radius and ulna ..	4 weeks	2 weeks
Colles's	5 weeks	2 weeks
Clavicle	4 weeks	2 weeks

It is well to place a patient suffering from fractured femur in a calliper splint so soon as the seventh week is past, and then no amount of perambulation will interfere with the length of limb. It is very necessary during the period of total restraint not to fall into the error of curiosity. Some surgeons are never content unless they worry the fractured ends week after week to see how

consolidation is getting on. Such procedure is as unscientific as the action of a cook who opens her oven every five minutes to see how the hot pot progresses. Until the normal period of the onset of consolidation, absolute rest should be ensured. In spite, however, of this injunction, the progress of the fracture should be watched, and deformity from time to time remedied. This can only be done by so arranging splints, that while one is off there remains a sufficient support for the fracture during inspection. There is no difficulty in this, and it should always be insisted on. If union is delayed, patiently wait without panic for three weeks longer, and give the seat of fracture meanwhile a severe pummelling with a covered pestle, after Mr. Thomas's method. Books warn us against putting pressure on riding fragments; and, of course, common sense would tell us not to press against a sharp end of bone. It is often, however, excellent practice to forcibly keep a riding fragment down, and only requires the exercise of ingenuity for its attainment.

When fractures take place into joints, great care must be taken to ensure perfect and uninterrupted rest. Avoid the text-book advice of passive motions. Time will not admit of my discussing this, but I may briefly state that if the joint becomes inflamed, motion will increase its severity; and if there be no inflammation of joint, motion will increase the quantity of secreted callus, and limitation of joint function will be thereby facilitated.

Just a word or two in regard to the treatment of special fractures. I have elsewhere treated more fully of Colles' fracture, but I would repeat here the necessity of at once thoroughly reducing the deformity. If this be done it will give but little subsequent trouble. The after-treatment enjoins rest for the wrist joint; five weeks incarceration, and no passive motions. Should, however, deformity meet the efforts of surgeons, this can be rectified even so long as nine months after injury, by means of a special wrench used by Mr. Thomas for club-foot. I was the first to attempt the reduction of old Colles' and Potts' fractures, and published a list of six successive cases. Since then Mr. Thomas has added to the number, and I have operated on fifteen patients. The only additional point to remember about Potts' fracture is that the ankle during treatment should be kept at right angles, otherwise tenotomy may have to be ultimately performed. Nearly every practitioner dealing with Potts' fracture counsels and practises delay during the swollen condition of the injured ankle. This is a bad practice, and for it should be substituted early and complete reduction.

We all know that despite the worst treatment, fractures will recover, and that oftentimes patients left to the tender mercies of nature will recover from even serious injuries. Now and again, however, failure will threaten, and we have to fall back upon principles which, if of advantage then, should be our routine custom. By aiming always at restoring the limb to the condition prior to accident, we do not merely avert non-union, but promote an elegant and artistic result.

INFANTICIDE: AN INQUIRY INTO ITS CAUSES, AND THEIR REMEDY.

BY FRANCIS VACHER, F.R.C.S.,

MEDICAL OFFICER OF HEALTH FOR BIRKENHEAD.

(Continued from page 214).

How to assist the unmarried mother, and help her to bear her burden, or relieve her of it, is a social problem most difficult to solve. The simplest course *appears* to be for the State or some charitable organisation to accept the

responsibility of bringing up all infants deposited for this purpose. This is a large and a costly undertaking, and the results in those countries where it has been tried are not calculated to recommend it. In St. Petersburg, where there is an enormous foundling hospital, the death-rate which obtains among illegitimate children, is as high as elsewhere, and the testimony of competent witnesses is that female unchastity is but lightly censured when the effects of it are so easily removable. It has also been found that when arrangements are made to enable any person to leave a child, without the person being seen or questioned, they will be used, to some extent, by the married poor. Thus the responsibilities and duties attaching to married life are interfered with, and early improvident marriages are encouraged.¹ What seems to me a far more desirable way of dealing with the difficulty, is by providing day-rooms, food and attendance for young children during the day. In most towns of any size there is a *crèche*, and probably wherever one has been opened it has found customers. *Crèches* are worked very cheaply, and cost little to establish, any ordinary house being suited for them; and if they were generally provided, unmarried mothers would have the accommodation they need, at least, all those who do not sleep on their employers' premises. For the children of domestic servants, and those similarly circumstanced, the *crèche* might afford lodging and maintenance by night as well as by day. One or two women always sleep on the premises, and little cribs are an essential part of the furniture, even in a nursery only used by day. As no one would wish to make a profit off such institutions, and money spent in maintaining them would be, at least, as well laid out as money subscribed to hospitals, the charge for each infant might be fixed at 2d. per day, or 4d. per day and night. A thorough system of efficient night and day nurseries would certainly do much to protect illegitimate infants from violence and neglect, or being done to death by a mercenary "adopter." There is a remedy that lies yet deeper, if one could only apply it. Were society to regard seduction as it regards the non-payment of a bet, and ostracize the seducer, seduction would cease to be a popular amusement for the wealthy, and the sad stories of Agnes Primrose and of Hetty Sorrel would not be repeated day by day. Yet, how easy it would be for society to treat the man as she treats the woman, and make both bear the burden and shame of their acts.

4. *Insurance of the Lives of Infants.*—All who have visited much among the poor know how very general is the practice of life insurance among them—insurance in so-called burial clubs. The agent may be seen going his rounds like the landlord's collector. The latter is commonly called the "rent man," and the former, by way of distinction, the "dead man." House after house is visited by

¹ "Considering the extraordinary mortality which occurs in these institutions, and the habits of licentiousness which they have an evident tendency to create, it may, perhaps, be truly said, that if a person wished to check population, and were not solicitous about the means, he could not propose a more effectual measure than the establishment of a sufficient number of foundling hospitals, unlimited as to their reception of children. And with regard to the moral feelings of a nation, it is difficult to conceive that they must not be sensibly impaired by encouraging mothers to desert their offspring, and endeavouring to teach them that their love for their new-born infants is a prejudice which it is the interest of their country to eradicate. An occasional child-murder from false shame is saved at a very high price, if it can only be done by the sacrifice of some of the best and most useful feelings of the human heart in a great part of the nation."—Rev. T. R. Malthus, on the Foundling Hospitals of St. Petersburg and Moscow.

him; in many he has his clients and gathers his weekly payments, and at others he canvasses. He is paid a regular percentage on what he brings in, and generally, if not always, a special bonus on all new business, so that he is directly encouraged to book as many fresh lives as possible; and the "quality" of the life is little considered. Of course old persons have to pay higher premiums; but as for babies and little children, they seem always to be accepted at a uniform rate, and there is little or no inquiry as to health and strength. The maximum sum for which an insurance may be effected on the life of a child under five years of age is £6; but just as there is practically no inquiry as to whether a life is a good one or a bad one for an office to accept, there is neglect to ascertain whether any insurance has been previously effected. Thus, when several burial clubs are doing business in the same locality, it may happen that the death of a young child is worth £12 or £18 to its parents or guardians; and there are conditions under which such a sum as this presents a terrible temptation—*e.g.*, when the family is something more than a quiverful, and the bread-winner, through scarcity of work, or ill-health, or hard drinking, is barely earning enough to pay the rent. The vision of these golden sovereigns is like a ubiquitous devil, urging the wretched parents day and night to do devil's work. Who can doubt that the poor thus tempted are occasionally guilty of murder by exposure or by drugging, and more frequently of murder by neglect? I have pointed out that the insured child may be puny and sickly even at the time the policy is taken out, and no extraordinary neglect likely to attract notice is required to kill such a one.

The remedy for this evil must of course be a change in the law, but quite a simple change will suffice. It would be very unwise by any act to thwart the prudence and forethought which moves the working classes so generally to subscribe to benefit societies, sick and burial clubs, etc. If life insurance is a praiseworthy precaution for the upper and middle classes it is even more praiseworthy for the poor. The removal of a father or mother by death ordinarily entails a direct loss independent of the cost of burial, and so does the death of any worker who has been helping others to live. In the case, however, of an infant or young child, the one legitimate motive for insurance is to provide funds for its burial. This being so, what I would propose is a short legislative measure prohibiting altogether infant life insurance by companies or firms, and empowering the Government to enter into an agreement to inter any child free of cost, on the parents or guardians taking out a policy on its life and paying a small monthly premium at the nearest post office. The working of such an arrangement would cost very little. Indeed, all expenses could be met and decent burial secured for less than half the payments now made to burial clubs in respect of young children. However, economy is a secondary consideration; the main recommendation of my proposal is that in this way all possibility of temptation to infanticide to obtain burial-club money would be done away with.

5. *Drunkenness of Parents and Guardians.*—Of all the causes of child murder, especially murder by omission, called in this paper constructive infanticide, the drinking habits of parents and guardians are the most familiar, the most flagrant, and the least amenable to remedy. "It is impossible," says Dr. Guthrie, a man of large experience among the poor, "to exaggerate, impossible even truthfully to paint, the effect of this evil, either on those who are addicted to it or on those who suffer from it—crushed

husbands, broken-hearted wives, and, most of all, those poor innocent children that are dying under cruelty and starvation, that shiver in their rags upon our streets, that walk unshod the winter snows; and, with their matted hair, and hollow cheeks, and sunken eyes, glare out on us wild and savage-like from patched and filthy windows." When the male parent is a drunkard the results are sad enough, for the tendency to inebriety is transmitted at least as frequently as tubercle is transmitted; but when the female parent is a drunkard, what chance of survival has the poor struggling infant life? Such a life is one continuous strife with death, and those who first succumb are the least unfortunate. Drunkenness, being one of the main causes of premature birth, the fight with death begins before independent life begins. Even if the infant be carried to full term it has been starved and drugged during the whole of intra-uterine life. Then from the birth the money that should clothe it and provide a warm home for it is spent in strong drink. If it be brought up at the breast the nourishment it receives from the birth is adulterated with strong drink: if it be brought up "by hand," what chance is there that a drunken mother will provide wholesome food? It is early taught the taste of alcohol to drown the cry of pain. Many a one the mother overlies in her drunken sleep. Many, while yet in arms, are taken out to beg, and, as soon as they can walk, sent out to beg or steal:

Till the stones of every street
Know their little naked feet.

And when death claims his victims from among this forlorn band the death is not certified as it might be:

Primary cause: Drunkenness of parent.

Secondary cause: Exposure, and want of proper food.

The cause certified and entered in the register is bronchitis, or pneumonia, or tuberculosis, or debility, etc., which is not untrue, but only a part of the truth. The result is that public opinion is never aroused to a sense of the waste of infant life which is going on, and year by year there is the same sacrifice of little ones—before their birth appointed unto death. Surely in their cold and nakedness, in their hunger and thirst, in their sickness and suffering and peril, they are made a spectacle unto the world, and to angels and to men.

Will anyone venture to say that such a wrong admits of no remedy; that this leaving helpless infants to the mercy of merciless drunkards is unavoidable? It is thought perfectly fair and reasonable when a man abuses the privilege of enfranchisement, to disenfranchise him, or when a man misuses his liberty to deprive him of it. It is obviously not less fair and reasonable, when parents prove by their conduct that they are unfit to exercise parental control, that they should be prevented from exercising it. How this might best be done would, of course, have to be properly debated, and due care taken that the rights of decent parents were safeguarded.

A ready way of attaining the desired end, as it appears to me, would be to empower magistrates, on a third conviction for drunkenness of a mother, or on a first conviction for drunkenness with neglect or cruelty to her infant, in addition to any penalty he may inflict, to order that the prisoner's children be taken out of her custody, and for a longer or shorter time placed under the protection of the guardians of the poor, or (at the father's request) of some female relative of good character. This may appear like cutting a Gordian knot, instead of untying it, but it will scarcely be said that it is contrary to the spirit of English law. At any rate, it is a bare suggestion—the details of

any measure the circumstances would warrant may well be left to legislators and lawyers.

I have, for the sake of explicitness, treated of the five causes of infanticide separately, but it is obvious that any child-murder may be due to two or more of these causes. Indeed, it is not only conceivable, but probable, that a child suffering from congenital disease may be also illegitimate, and insured in a burial club, and have a drunken mother. Generally, it may be said that the greater the number of death-factors menacing an infant's life, the less the chance of its survival. Owing to the causes being so often combined, it is difficult to estimate their relative fatality. However, so far as I have had opportunity of judging, I believe the five causes I have named are fatal in an order inverse to that given, the drunkenness of parents and guardians being the most frequent cause of infanticide, and early improvident marriages the least frequent.

DYSMENORRHOEA.¹

BY AMAND ROUTH, M.D., B.S. LOND., M.R.C.P. LOND.,

ASSISTANT OBSTETRIC PHYSICIAN, CHARING-CROSS HOSPITAL; PHYSICIAN TO THE SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.

(Continued from page 212.)

Constitutional Causes of Dysmenorrhœa.—These are rather numerous, and where not actually the cause, may seriously aggravate the pain due to local conditions. Anæmia and chlorosis are very common causes of the spasmodic type, and with them may be associated exhausting diseases, such as diabetes, Bright's disease, or phthisis. The specific fevers often cause dysmenorrhœa, by setting up a low form of endometritis, and both typhoid and scarlatina are apt to lead to cirrhotic change in the ovaries producing dysœotocia. Of the more general diseases, acute and chronic rheumatism are most likely to leave pelvic mischief from the fibrous tissue of the ovary becoming affected.

Constitutional Treatment of Dysmenorrhœa.—As I have said, successful treatment depends upon finding and removing the cause. As a rule, it is irrational to mask the symptom of pain by giving opiates, whether by mouth, rectum or subcutaneously, though where we are called in during a severe paroxysm, it may be necessary, but I would suggest that we should always add *atropine*, *belladonna*, or *hyoscyamus*, which relax muscular spasm, and enable us to use smaller doses of opium, and to avert sickness and constipation. The main objection to opium and chlorale is that their monthly repetition tends to their abuse. This objection holds even more strongly as regards alcohol, access to it being easier. *Nitro-glycerine* and *amyl nitrite* are excellent drugs for spasmodic cases, their action being prompt and effectual, though often only temporary; they answer best in dysmenorrhœa due to fibroids, especially when the catamenia is scanty. The *bromides* are indicated in ovarian dysmenorrhœa, and especially in those cases where menorrhagia of tubal or ovarian origin exists. *Cannabis indica* in $\frac{1}{4}$ to $\frac{1}{2}$ grain doses of the extract, or in 2 to 10 grains of the tannate of cannabin are valuable as a substitute for opiates, and are especially useful when menorrhagia coexists, being most efficacious in obstructive dysmenorrhœa, due to fibroids. It is well to use one chemist's (e.g., Squire's) preparations, but, unfortunately, besides its variable strength, it varies much in its effect upon individuals, and should therefore be given with caution.

Tr. cardam. co., with sp. chlorof., make an agreeable combination, and is of signal service in simple cases. Tr. chlorof. co., or sp. etheris co., act similarly. Their effect is much enhanced by adding large doses of liq. amm. acetat. ($\frac{3}{4}$ j. to $\frac{3}{4}$ ss.), both in spasmodic and congestive dysmenorrhœa. A favourite prescription is: R—Tr. cardam co., $\frac{3}{4}$ ss.; sp. chlorof., \mathcal{M} xx.; liq. a. acet., $\frac{3}{4}$ ss.; Tr. bellad. \mathcal{M} x.; aq. cinnamon, ad. $\frac{3}{4}$ i. If the pain is very acute, Battley's solution goes well with this, and to encourage sweating, a drop of sol. nitro-glycerine (one per cent.) may be added (with ammonia). Bromides may be substituted for the belladonna if indicated. A week's use of guaiacum, or salicylate of soda, will often prevent dysmenorrhœa of rheumatic origin; whilst for the frontal and migraine type of headaches, which so often accompany the onset of catamenia, nothing answers so well as antipyrin. In fifteen-grain doses, to be repeated in two hours if necessary. In all cases of expected dysmenorrhœa, the bowels should be freely evacuated.

Measures auxiliary to the above therapeutic remedies should not be admitted. Rest before and during the period is all important, as also is warmth of skin; much relief may often be afforded by warmth applied over the abdomen, or to the feet by any of the usual methods. Heat should not be applied solely over the sacrum, as it is then apt to check the menstrual flow. After the period is over, opportunity is afforded for preventive treatment. Anæmia and chlorosis may be dealt with by iron, arsenic, acetate of ammonia, and purgatives, and much may be done in the three weeks' interval to make the next period freer and less painful. Distant organs should be treated if affected, and their functions regulated, especially those of the liver, skin, and bowels. Abuse of alcohol, sexual excess, mental or physical overwork, improper or deficient food, unsuitable or tight clothing, may also be items whose avoidance may do good in a given case.

Local Treatment.—There remains now the treatment of the local causes of dysmenorrhœa. We will first assume that we have found no flexion, version, or descent, no past or present metritis, para- or peri-metritis, no fibroids, no subinvolution, no ovarian or tubal disease, and that we therefore proceed to an intra-uterine examination. We may then find that acute pain of a radiating character is caused by the passage of the sound, either as it passes along the canal, or when it touches the fundus (which it must be remembered is always slightly sensitive), and that blood issues from the womb when the sound is withdrawn, no difficulty having been experienced in its introduction or withdrawal. This would point to either corporeal or fundal endometritis, as my father first pointed out, and would require rest, intra-uterine treatment, and medicine according to circumstances. Again, we may find the mucous membrane of the uterus so irritable that the sound will cause a spasmodic contraction exactly resembling that which the patient has at her period, analogous probably to spasm of the glottis when irritated by a foreign body. If we can lessen this hyperæsthesia of the uterus, we shall cure our patient. The spasm here assumed to be set up is not of a ring of muscular fibres only, as is said to occur in spasmodic urethral stricture, or as occurs at the vulvar orifice in vaginismus, but to be a real and painful constriction of all the uterine muscles tending to *expel*, rather than to *grip*, the sound being often forced out again, instead of held tightly as in obstruction. Again, we may find that the sound

¹ A Post Graduate Lecture, delivered at Charing-Cross Hospital, on January 6th, 1888.

will not then readily pass, and to make sure that it does not catch in the mucous membrane of the endo-cervix, we should use a rounded bougie, No. 8 or 9. If a marked flexion exist, the fundus must be elevated on the finger, or the cervix drawn down with a hook or toothed forceps. Occasionally we may find a difficulty in passing through the os uteri externum, especially with a conical cervix.

The old method of division of the cervix, or "hysterotomy," is now rarely (and should be never) employed, though a bilateral nick on either side of a small external os uteri is sometimes of use, and can be done with either a knife or Küchenmeister's scissors. After any incision such as this, rarely necessary for dysmenorrhœa alone, some lint steeped in iodine and glycerine should be pushed into the cervix for twenty-four hours. For dilating the uterus *above* the external os, hysterotomy has now been discontinued, and the great dangers arising from hæmorrhage and sepsis thereby removed. Tents, such as sponge, sea-tangle, or tupelo, are also unnecessary for the cure of dysmenorrhœa, and another source of danger is thereby removed, pyrexia rarely following the methods now employed. The dilators now used are mainly copied from those used for urethral strictures, the most useful and most generally applicable, and certainly the safest, being some of the many forms of bougies, corresponding in sizes to the male bougies. There are two main types, the one of metal, with a large curve, suitable for passing on the finger, without a speculum if preferred; and the other shorter and less curved, made of wood, horn, or vulcanite, for use when the uterus is drawn down. Those of Matthews Duncan, or Edis, are the best of the metal bougies; those of Hegar or Leiter of the shorter types. Great care must be employed in using these dilators, no undue force being used, and the direction of the canal must be known. We must avoid carrying septic material from the vagina up into the uterus, as endometritis may be set up, with its sequelæ. To avoid this, the vagina should be syringed by the nurse with an antiseptic lotion, or mopped out by the physician with cotton wool, dipped in liquor hydrarg. perchlor., B.P.

To cure *spasmodic dysmenorrhœa* the dilatation required is slight, the passage of bougies up to No. 12 usually being sufficient. By avoiding the use of a speculum, and using the metal bougies, previously warmed and oiled, these can be passed in spite of the existence of an ordinary hymen without damage, the patient lying on her side. If the vagina be capacious, and assistance is at hand, it saves time to draw down the womb and pass the bougies through a Sim's duck-bill speculum, or a Neugebauer's, or Barnes', or Meadow's, if the patient be on her back. The bougies may be passed successively at the same sitting, or on several consecutive days. A larger size should not be passed till either the pain has lessened, or, if the patient be anæsthetized, till the grip of the bougie, then in utero, has become loosened. Whichever plan be adopted, the process should be completed about three days before the expected period, which will probably be anticipated. It is advisable to paint the endometrium with lin. iodi., or pure carbolic acid, after the dilatation, and to place a glycerized tampon in the vagina up against the cervix.

In *obstructive dysmenorrhœa* dilatation must be carried further, and more caution must be used. The patient may need preparation by rest, purgation, hot vaginal iodized douches, and, if congestion be present, blood should be drawn from the cervix, and glycerine tampons inserted for the week previous. Here Leiter's or Hegar's dilators up to

No. 18 or 20 may be required, and an anæsthetic given, though cocaine (Head Moore's cones) will make the pain almost bearable. Rest in bed, with daily hot vaginal douches, is necessary for at least a week afterwards. This treatment will almost always cure membranous dysmenorrhœa, though the condition may return and the dilatation be again necessary, but if pregnancy supervene the cure is usually complete. In some cases an intra-uterine stem may be necessary to prevent contraction recurring.

Treatment of Displacement.—I am here dealing with displacements only in so far as they are the causation of dysmenorrhœa. I have shown that a flexion may exist and yet not be the cause sought for—a less obvious condition being the real cause. We must therefore examine every case carefully, and not be satisfied with a condition which may have been present from foetal life. If we find a true obstruction at the point of *supra-vaginal* flexion it must be dealt with as an ordinary stenosis, by dilatation, but the tendency to recurrence is much greater when the obstruction occurs at the point of flexion than elsewhere, so that it *may* be necessary to introduce an intra-uterine stem for a short period to allow free exit to the uterine contents, by keeping the canal patent and the uterus at its normal curve. Versions *per se* never cause true obstruction. Intra-uterine stems must be used with great caution. Formerly, their method of introduction, or rather absence of method, was the cause of frequent accidents, or even death, so that this generation is only now awaking from the dread of their very name. Thus they used to be forcibly introduced in the out-patient department at our hospitals, the patient then walking home, metritis and peri-uterine inflammation being often the result. Till recently, again, it was thought necessary to first dilate with sponge or laminaria tents, often thus provoking septicæmia, and not so very rarely pelvic abscess, or even death. Now we consider both these methods bad, and insist upon a strict preparatory treatment.

The use of stem pessaries must be rigorously excluded in all cases of metritis or peri-uterine inflammation, either present or recent, as well as in every case of endometritis. We choose the time when there is least pelvic hyperæmia, which is about ten days after a period is over. We enjoin rest in bed for a day or two beforehand, with free purgation, and we relieve any congestion by means of glycerine tampons, hot vaginal douches, and scarifying the cervix in some cases. At the time of introduction we purify the vagina, straighten the uterine canal by drawing down the cervix, and dilate it by passing a series of warmed and oiled bougies until we are sure the selected stem will easily pass; we then apply carbolic acid to the endometrium on a Playfair's probe to disinfect the uterine cavity and lessen its sensibility, and then gently introduce the stem on a suitable holder, taking care that the length of the stem is at least one-third of an inch less than the total inside length of the uterus, to avoid contact with the tender fundus. Rest in bed must follow for at least a week, and on the sofa till *after* the next period, which is usually anticipated, after which the patient may resume her ordinary occupation, using throughout hot antiseptic vaginal douches.

My favourite stems are simple glass or vulcanite ones, or the compound stems bearing the names of their authors—Meadows, Wynn Williams, or my father's. The choice depends of course upon the condition of the uterus. It should be clearly understood that the use of intra-uterine stems is always a *dernier ressort*; that they are only to be

justified where serious obstructive dysmenorrhœa exists, which has recurred after ordinary dilatation, or in those rare cases of grave constitutional disturbance arising from acute flexions with prolapse, or in a few cases of ante flexion with sterility, where every other method of treatment has failed.

With these limitations and precautions I have not had any anxiety in the use of these stems, rarely having the least rise of temperature even, and have succeeded in curing cases where other measures have failed.

Inflammatory Dysmenorrhœa.—Want of time prevents me dwelling at all upon the treatment of pelvic inflammatory states beyond pointing out the necessity of absolute local and general rest, without which all treatment would fail.

Congestive Dysmenorrhœa.—I have already alluded to the cure of congestion of the uterus when due to, or aggravated by, prolapsus, by means of vaginal pessaries. Many cases, however, do not need these. Rest alone will cure some. Astringent lotion, such as tinc. iodi, tannin, sulphate of zinc, alum, using of each 3 i. to the O i. of hot (105° F.) water, will often both relieve the congestion and give tone to the vaginal walls.

Of pessaries the best is a Hodge Lever pessary, which can be moulded to fit almost every condition when made of soft wire and india-rubber, and a more permanent vulcanite, or hollow metal one, can be made from that as a copy. Rings of all kinds should be avoided if possible. Vaginal douches should be used with a syphon apparatus, the patient being recumbent. Scarifying, or leeching the cervix, and glycerine tampons are indicated in bad cases, and I have seen much good arise from the use of Leiter's tubes with hot (120° F.) water passing through them, and placed along the lower dorsal and lumbar spines for several hours daily.

Medicinal treatment should be directed towards acting on distant excretory organs—skin, liver, bowels, kidneys—and ergot should be given to drive the excess of blood from the uterus. Small doses of hydrarg. perchlor. often act well. The following pill, to be given between the periods, often relieves pelvic congestion: R—Ergotin, gr. i.; ext. aloes aquos., gr. $\frac{1}{4}$ – $\frac{1}{2}$; ext. nux vom., gr. $\frac{1}{2}$; hydrarg. perchlor., gr. $\frac{1}{20}$; ext. bellad., gr. $\frac{1}{3}$. M fiat pil. bis die sum; with Hunyadi Janos early in the morning. I cannot here allude to the treatment of fibroid, especially as Apostoli's method is still *sub judice*.

In conclusion, it will of course be understood that while for convenience I have grouped cases of dysmenorrhœa under these heads, it is exceptional to find any one case so clearly defined as to be treated solely from one point of view. Long-standing cases, functional at first, tend surely to hypertrophic, or congestive changes; and cases may be of such antiquity, or be so complicated, as almost to baffle us. Let us, however, never despair; let us try to find the real starting-point of everything, and let us do nothing rashly; but let us act patiently, and with that confidence in our own treatment which inspires confidence on the patient's part towards us, and we shall rarely fail to cure those under our care.

SKETCH OF THE CORONER'S COURT, AND ITS PRINCIPAL RELATIONS TO THE MEDICAL PROFESSION.¹

BY JOHN EATON, M.D.

HAVING observed in the medical journals, of the past fourteen years or so, the frequency of paragraphs regarding coroners, coroners' courts, and inquests, with notes of

inquiry in reference to curious or obscure points in the history, functions, and jurisdiction of coroners' courts, and complaints of the misbehaviour and incompetency of certain coroners, their occasional discourtesy to medical witnesses, misleading remarks to juries, the frequency with which unnecessary inquests are held, and the frequently irrelevant and absurd verdicts of juries in consequence of skilled medical evidence not having been called, it has occurred to me that a brief sketch of the coroner's court and its present constitution, with an account of its relations to the medical profession, might prove useful and interesting, and might enable us more justly to decide the desirability or not of the office of coroner being confined to the medical profession, or of as many medical men as possible endeavouring to become coroners; and of the reforms which are necessary in order to remove the various anomalies and anachronisms which exist in connection with that ancient, respectable, and important institution—the Coroner's Court.

The task which I have thus undertaken is one which many members of this society are doubtless more able to accomplish, but I hope by attempting it to elicit the opinions of such, and consequently to increase and confirm our knowledge on a subject of very great importance to the medical profession, and to prevent the too-frequent quotation of authorities from interfering with the narrative. I may here mention that the facts of this paper are obtained chiefly from the *British Medical Journal* since 1872, the "Medical Directory" (1887), an article in the "Encyclopædia Britannica" (9th edition), Archbold's "Justice of the Peace" (7th edition, 1875), Sir John Jervis' "On Coroners" (4th edition, 1880), Stephen's "Digest of the Law of Evidence" (4th edition, 1881), the Coroners Act 1887, and other sources which will be indicated as we proceed.

The coroner's court is one of the most venerable of our legal institutions. The exact date of its origin is not known, but it has been in existence for at least a thousand years; and like much of our common law, the office of coroner seems to have been of Saxon origin. According to Sir Edward Coke, sheriffs existed in this country, as officers of the consul, in the time of the Romans, and it has been supposed that the office of coroner may have been established about the same time as that of sheriff, and thus have existed prior to the Saxon period.

Rapin, in his "History of England," notes the similarity of the customs practised in England at the beginning of the 18th century to those that the Anglo-Saxons had practised there, which they had brought with them from the northern countries, and lastly from Germany. And an English historian, Brady, quoted by the same high authority, affirms that until the Norman Conquest the laws of England and Germany were identical. Alfred the Great collected an admirable code of laws, consisting of selections from the judicial laws of the Old Testament, from those that had been enacted by Ina, King of Wessex, and Offa, King of Mercia, in their respective kingdoms, and others of his own, adapted to the circumstances of his people. He was exceedingly anxious to administer justice to his people, and finding that, notwithstanding all his precautions, the rich and powerful were apt to oppress the poor and dependent, he established juries in criminal cases, ordering that in such cases twelve men chosen for that purpose should determine concerning the fact, and that the judge should give sentence according to their verdict. This was evidently equivalent to the establishment of the chief feature of the coroner's court, and doubtless consti-

¹ Read before the West Cumberland Medical Society, at Whitehaven, May 25th, 1887.

tuted at that rude and remote period a considerable safeguard against injustice to those who were accused of crimes. Sir John Jervis in his book "On Coroners," page 2, states that coroners existed in the time of King Alfred, for that king punished with death a judge who had sentenced a party to death upon the coroner's record, without allowing the delinquent liberty to traverse or appeal on the point of law. We find also that coroners, as officers of the realm, are mentioned in a charter, dated A.D. 925, granted by Athelstan, in the first year of his reign to the Monastery of St. John of Beverley, but though the office of coroner was established thus early, according to Stow, they were first appointed for every county in England by statute of Westminster (3 Ed. I.) in 1275.

The coroner is, therefore, a very ancient officer of the Crown in Great Britain, engaged at common law, principally with pleas of the Crown, whose chief duty is to hold and preside over a court of inquiry and record; to ascertain the cause of sudden, mysterious, or violent deaths. From the Statute, *De Officio Coronatoris*, it would seem that coroners had authority to inquire regarding cases of rape, house-breaking, prison breach, and arson; but C. J. Cockburn, in the case of *Regina v. Herford*, says, "that the office of coroner, with reference to felonies, is limited now to cases of homicide on the view of the body," and that decision has now been accepted as law by Lords Coke and Hale, and adopted by C. B. Comyns in his "Digest" (because it had never been exercised since Magna Charta, signed by King John, 15th June, 1215). It is still, however, the duty of a coroner to inquire of any hidden treasure that has been found; and he has power to try on suspicion anyone suspected of having found such treasure; and anyone finding such treasure who fails to make it known to the coroner of the district, through his usual officers, the peace officers of the district, is liable to fine and imprisonment. The duty of the coroner, however, to inquire regarding shipwrecks and treasure trove has been nearly superseded by the provisions of the Merchant Shipping Act, 1854, and clause 44 of the Coroner's Act, 1877, expressly abolishes the jurisdiction as to fish, though the practice was obsolete.

Up till last year the coroners had yet power to inquire of wrecks, of royal fishes—as sturgeons—and of whales, and to secure their value to the Crown. Except in London, where the judgment is given by the recorder, it is his duty yet to be present, under a penalty of fine or imprisonment, at the sheriff's county court, to pronounce sentence of outlawry against anyone who has refused to be amenable, or to abide by the justice of that court which has lawful authority to call him before it, on or before the fifth county court, or day of exaction under the writ. Coroners can also execute process for the sheriff, when the latter is incapacitated by interest in the suit; where there are two sheriffs, the one can, in that case, act for the other; but when a sheriff dies, the under-sheriff, and not the coroner, has power to act until another sheriff is appointed. When coroners are incapacitated by interest or otherwise, *elisors*, appointed by the officers of the court, act for them; but when there are several coroners in the district, those not so interested can act for the others. In all proceedings against the sheriff, the process should be directed to, and executed by, the coroner.

In the reign of Edward III., the office of coroner was considered very high, honourable, and responsible. By the Statute of Westminster, the first (3 Ed. I., c. 10), it was enacted that none should be chosen for the office but

lawful and discreet knights,¹ and in the time of Edward III. there is an instance of a man being removed from the office, because he was merely a merchant. Subsequently, it was deemed sufficient if a man had lands to the value of £20 per annum, which was the amount entitling him to be a knight. Blackstone complains that in his time (1743—1780) the office had changed from its original dignified and honorary character, and had become a paid appointment in the public service. He seemed to think that the coroners of his time were a very mercenary set of men, and had desired to be chosen to the office for the sake of its perquisites, for fees for attendance had been granted by the statute (3 Henry VII., c. 1), of which Sir Edward Coke also complained heavily, though since his time those fees have been much increased. It is interesting to note the deprecatory remarks of such authorities as Coke and Blackstone, merely because fees were accepted for work done, as it is now universally acknowledged that important work ought always to be well paid for, and the coroner, like other public officers, justly receives payment for his services.

Although as the law stands at present, a retired tradesman, an auctioneer, a land agent, a house agent, or other person, with influence to affect the freeholders of the country, may become a coroner. The coroner is generally a qualified legal or medical practitioner. The property qualification has been virtually dispensed with, and the county is liable for any penalties that may be incurred officially by the coroner. The coroner is at present appointed by the freeholders of the county or district assembled in county court, but the possession of the site of a pigsty will confer the right of voting, and the freeholders, as a class, are wholly unqualified to judge of the ability of a man to be a coroner. The office has always been elective, and is held for life, and curiously enough when on the polling day, the sheriff has declared the successful candidate, his decision is practically final and irreversible, even though the sheriff may have admitted votes wrongly.² A coroner, however, vacates his office when he is made sheriff or verderor (the latter being an officer sworn to keep the assize of the Queen's forest, and whose duty is to take care of the *vert* and venison). He may be removed for inability or misbehaviour in his office by the Lord Chancellor, or by the writ, *De Coronatore exonerando*, for sufficient cause assigned as old age, sickness, other business engagements, etc. Under the Municipal Corporation Act,³ borough coroners are still paid by fees, as was the case with county coroners at an early part of the present reign, but by Act 23 and 24, Vic. c. 116, the system of paying county coroners by fees was abolished; and they are now paid by salary out of the county rate, calculated on the average amount of the fees, mileage, and allowances usually received by the coroner for a period of five years, and the calculation is to be revised every five years. The Home Secretary is to decide when the coroner and the justices cannot agree.

¹ Clause 12, Coroners Act, 1887, omits the statutory provisions as to a county coroner being a knight (*see* 3 Ed. I., c. 10), and having other qualification, which are now obsolete.

² *Regina v. Diplock*, 34 J.P., 118; Archibold's "Justice of the Peace," vol. i., p. 391—5.

³ The Corporation and Test Act, passed in 1661, was repealed May, 1828; The Corporation Reform Act, for regulating Municipal Corporations in England and Wales, 5 and 6 William IV., c. 76 (1835), was amended in 1869. Charters of right were first granted in England to various towns by Edward the Confessor (1042), and Henry I. granted Charters in 1100.

Coroners are of four kinds: official coroners, franchise coroners, coroners by election, and borough coroners.

The official coroners are the Lord Chief Justice of the Queen's Bench, and the Judges of the High Court of Justice, who are sovereign coroners, and may in any place in the kingdom exercise the jurisdiction of the coroner, but the Lord Chancellor is *ex-officio* censor of coroners. The Lord Chief Justice, therefore, in his capacity as general coroner of the realm, is liable to be censured, admonished, and deprived of his office, with all its dignity, and with such few emoluments as may attach to it (*British Medical Journal*, vol. 2, 1882, p. 376) by the Lord Chancellor.

Franchise coroners are those within particular liberties, towns-corporate, lordships, manors, universities, and franchises over which the lords or heads of corporations are empowered by charter to act themselves (when they must describe themselves as coroners), or to create their own coroners, and no subject can claim this franchise except by special grant from the crown, but franchise coroners can, by prescription, in many cases appoint a deputy with consent of the lord of the franchise. The mayor of London is by charter coroner of London.

The cinque ports (Dover, Hastings, Hythe, Romney and Sandwich, Winchelsea and Rye), from their great antiquity, have their own coroner.¹ The dean and chapter of Westminster have their own coroner, who by their appointment is coroner for the city and liberty of Westminster. In the stanneries² in Cornwall the wardens are coroners. The Clerk of the Crown still retains the title of Queen's Coroner, and before the passing of the Prisons Act, 1865, he had jurisdiction over matters arising within the Queen's Bench Prison. There are other exclusive jurisdictions and corporations for which coroners are appointed, the principle of such jurisdictions being that of the verge, and that of the admiralty.

The coroner of the verge, or of the royal household, once had exclusive jurisdiction within a circuit of twelve miles round the residence of the court, but is now confined to the actual precincts of the residence of the sovereign, and two hundred yards from those precincts, for the time being. By statute (33 Henry VIII., c. 12), the Lord Steward, or Lord Great Master of the Royal Household, is, *ex-officio*, always coroner of the verge. In some cases the coroner of the county has concurrent jurisdiction with that of the coroner of the verge; as when a person had been killed within the verge of the court, and the king had removed his court before an inquisition had been taken by the coroner of the king's household, it was enacted by the statute *Articuli super cartis* that the coroner of the county and the coroner of the verge must act together. But Clause 29, Coroners Act 1877, subsection 2, removes the ambiguity as to the jurisdiction of the coroner of the queen's household when the death arises in a palace in which the queen is not then abiding; subsections 4 and 9 restrict the jurisdiction of the coroner of the queen's household to the limits of the palace, thus throwing the two hundred yards into the jurisdiction of the county coroner; subsection 3, directing the return of the jury by such officer of the queen's household as may be directed

to summon the same by the warrant of the coroner, is not at present statutory.

The coroners of the Admiralty have exclusive jurisdiction of matters arising on the high seas, and by statute (15 Rich. II., c. 3), the coroners of the Admiralty have now jurisdiction concurrently with the coroners of the county of the death of man and maihem,¹ in great ships hovering on the main streams, in great rivers, *infra primos pontes*.

As we have seen, the statute of Westminster² first (3 Ed. I. c. 10), enacted "that through all shires efficient men shall be chosen to be coroners," and there are many interesting particulars in reference to the office of coroner which we will endeavour to state in as condensed and clear a manner as possible, as we consider them essential as an introduction to the other portions of this paper. Some counties have six, some four, others two, and others only one coroner,² but the Lord Chancellor can issue a writ for the election of one or more coroners, or as is now the practice, the county may, upon the petition of the Justices at Sessions to Her Majesty in Council, be subdivided into districts, and it is important to note that "detached parts of a county, riding, or division, shall be deemed to be within that county, riding, or division of a county by which it is wholly surrounded, or where it is partly surrounded by two or more counties, ridings, or divisions within that one with which it has the longest common boundary."

Borough coroners are those appointed by the council of every borough in England and Wales in which a separate court of Quarter Session is held, and must not be aldermen or councillors of the borough. Coroners are *ex-officio* magistrates and conservators of the Queen's peace; their most important duty is to hold inquests on view of the bodies of any persons slain, or suddenly and mysteriously dead, to ascertain how the death occurred; and if anyone be culpable, to cause the person to be taken, delivered to the sheriff, and committed to gaol. Those concerned not culpable to be bound over to appear as witnesses before the justices. He has also to inquire regarding all deaths that occur in prison; to satisfy the public that the death was from natural causes, and not *per dure gard*, or violence, or ill-treatment in prison. He must also within twenty-four hours after a public execution, in any prison within his jurisdiction, hold an inquest on the body, to ascertain its identity, and whether judgment of death has been duly executed.

When a lunatic dies in an asylum, or licensed house, or under the care of any person, that person must forward to the coroner, within two days of the death, a proper certificate of death, and if the latter thinks that any reasonable suspicion attends the cause and circumstances of death, he must hold an inquest on the body. When an infant under one year of age dies in a house registered under the Infant Life Protection Act, 1872, notice must be given of the death within twenty-four hours to the coroner by the person registered, and if no satisfactory medical certificate is furnished to the coroner, he must hold an inquest.

By the Mines Regulations Act special provisions exist as to coroners' inquests on deaths from accidents or explosions in mines. The coroner can, at once, take evidence as to the identity of the body, and order its

¹ These ports being nearest to France were considered the keys of the kingdom, and were placed under special barons or wardens, whose special jurisdiction was, however, abolished in 1855.

² Courts in Devon and Cornwall for administering justice among the tin miners, confirmed by 33 Ed. I., 1305, regulated by Parliament 1641, and frequently since. A "Stannaries Act" was passed in 1869.

¹ Maihem or mayhem means depriving a man of a member necessary for defence in fight.

² See "Medical Directory," 1887.

interment; but unless the Inspector of Mines for the district, or some person on behalf of the Secretary of State, is present to watch the proceedings, the coroner must adjourn the inquest, so as to be able to give the inspector at least four days' notice in writing of the time and place of holding the adjourned inquest; but if not more than one person has been killed by such an accident or explosion, and the inspector has received not less than forty-eight hours' notice of the time and place of holding the inquest, it will not be imperative to adjourn the inquest, if the majority of the jury think it unnecessary so to adjourn. If, at an inquest at which an inspector is not present, evidence is given of any neglect causing or contributing to the explosion or accident, or of any defect in or about the mine, appearing to the coroner or jury to require a remedy, the coroner shall send to the inspector of the district notice in writing of such neglect or default. It is also the duty of the coroner not to allow any person having an interest in, or employed in, or in management of the mine where the explosion or accident has occurred, to be sworn or to sit on the jury, but such a person may be present at the inquest. I have known a case where it was suggested that the presence of the manager of the mine might intimidate the witnesses, and yet the coroner allowed him to be present, which was only fair, as he might have been personally implicated in the verdict.

FROM GENERATION TO GENERATION:

A PRELUDE TO THE STUDY OF HEREDITY.

By R. A. DOUGLAS LITHGOW, LL.D., M.R.C.P. ED., F.S.A.,
F.R.S.L., ETC.

(Continued from page 217.)

General Disorders of Nutrition.—The series of disorders which I now propose to consider may be regarded as entirely constitutional, and, therefore, all the more likely to be hereditary. It must be admitted that there are different types of physiological constitutions manifested among various healthy individuals; yet so elastic and indefinite are the characters by which these are distinguished, that every degree and variety of transitional forms are frequently manifested. In the same way, no hard and fast line of demarcation can be laid down as dividing purely physiological from pathological conditions, and as even health itself is an arbitrary relative condition, so physiological phenomena merge imperceptibly into those which are pathological. In this group of constitutional disorders "the stability of the dynamic equilibrium of the vital processes is different from that which subsists in health—depends immediately upon the morbid change which the vital processes have undergone in regard to their force and direction, and is, therefore, ultimately bound up with the very essence of every constitutional disorder." It is quite possible that an individual suffering from one or other of these nutritive disorders may for a long time appear in excellent health, until, in fact, some critical epoch, or external influence, or some inter-current malady will develop the morbid tendency into a well-marked pathological condition. In the production of these, as in that of other, diseases or disorders, two sets of causes are usually recognised—viz., external or exciting, and internal or predisposing. Of the former we must be careful to exclude, in general terms, those of an infective or toxic

character, from those denominated "autogenetic," which may be said to consist in some deficiency, unsuitableness, or excess of the normal vital stimuli, as light, air, warmth, food, exercise, etc.¹ Of the internal or predisposing causes which influence the development of the general disorders of nutrition, I may mention in the first place, as of most importance, inheritance; then age, sex, physiological constitution, errors of development and pathological processes, and psychical influences. Of these I am more concerned, on the present occasion, with inheritance, the influence of which is so emphatic and unmistakable as to often render all other possible causes as of no account. It should be remembered that hereditary constitutional maladies may be indiscriminately inherited from either parent, but that when both parents have the power of transmitting the same constitutional condition or anomaly, the transmission becomes almost absolutely certain. Heredity is the rule; non-heredity the exception. The exception may be illustrated by the following facts:—The influence of an affected parent may be neutralised or rendered dormant by that of the other one: by atavism or reversional heredity a whole generation may be passed over, the inherited influence reappearing as potently as ever in the next: some members of a generation may be affected, others spared, owing to the influence of one parent being transmitted to certain members, whilst that of the other is transmitted to others, or that of fathers to sons, of mothers to daughters, or of fathers to daughters, and of mothers to sons. As Immermann says: "The parents need not always exhibit visible signs of their constitutional vice at the moment of conception: a general disorder of nutrition which is latent in them is as capable of being transmitted as one that is apparent. The inherited vice often remains latent in the infant, and does not show itself until a later period—till the age at which it showed itself in the parent. Hence, it follows that age as well as sex may favour or oppose the influence of heredity; that it is more correct to speak of the constitutional vice itself, than of its manifestation, as being subject to inheritance." By the general law of heredity is therefore meant, that the most essential qualities of the parents are transmitted to their children, unless neutralised by other internal or external influences, and this law affects alike the domain of physiology and of pathology. Children resemble their parents, not, however, 'as stiff copies of equally rigid prototypes, but as variable magnitudes whose variations obey the same type.' From this it will be seen that it is the entire physical life which is reproduced—the constitutions of the parents, with all their natural changes, which are generally transmitted: and so, even as a normal constitution is transmitted, so is a constitutional vice repeated in the offspring.²

I shall now consider some of these general disorders of nutrition with regard to their inheritance.

Anæmia.—Different persons have relatively unequal quantities of blood, and different persons are differentiated still further from each other by relative differences in the state of physical nutrition. Healthy constitutions may, therefore, be divided into those which are rich in blood or vigorous, and those which are spanæmic or feeble, according to these two sets of phenomena. When it is remembered that an individual constitution is the result of heredity, and the influences of his environment during foetal and extra-uterine existence, it will readily be con-

¹ Immermann.

² Ziemssen.

ceded that certain forms or types of weakly, feeble constitutions, which so frequently develop pathological anæmia, are often inherited from either or both parents. The fact of whole families being characterised by a predisposition to anæmia in its many forms is proof enough. How frequently is this the case! And there cannot be a shadow of a doubt that whether we regard "the average power of renewing the constituents of the blood, the average rapidity with which they are utilised in nutrition and growth, and finally, the average amount of the blood store (as the resultant of the first two elements)," they are singly and collectively subject to the influence of heredity. The exciting causes of anæmia are numerous and important; but whether we regard the affection itself in its physiological or pathological aspect, we find in one as in the other almost invariably a predisposition which is inherited more or less, in differing degrees, and that the physiological predisposition will very readily become developed into the pathological.

Chlorosis.—To the influence of certain predisposing causes inherent in the patient's constitution we must trace the source of chlorosis; and these are principally—sex, age, and heredity, which have the greatest share in its development. Sex and age are, in this affection, of pre-eminent importance, inasmuch as no combination of causes from which these are omitted are competent to develop it. In fact, youth and the female sex are indispensably necessary. With regard to age, chlorosis usually affects young girls between the ages of fourteen and twenty-four, during the time when sexual evolution occurs. Of no less importance, however, is the influence of heredity, as an inherited predisposition must be admitted to exist in many, if not the majority of cases. Moreover, the heredity of chlorosis may be taken as an example of certain inherited affections which usually manifest themselves at the same period of life at which they affected parents or ancestors, and which have been explained on the hypothesis of latent characteristics contained in the individual in the germ state, and which come to light only under definite conditions, and at some particular point of his development, and this particular moment corresponding with a similar moment in the progenitors. Hereditary diseases are, in fact, good instances of heredity at corresponding periods. Thus chorea, which usually makes its appearance in childhood, chlorosis in youth, consumption in middle age, gout in old age, are naturally hereditary in the same periods. With regard to the inherited tendency to chlorosis, the disease is often found breaking out in the majority of, or in all, the female members of a family from one generation to another, oft repeated, and at corresponding periods of life, and this independent of the external circumstances amid which they may have been brought up. Previous to the development of the chlorotic attack, predisposed girls have usually manifested anæmia, and functional irritability of the nervous system, but not invariably, as the attacks have been known to occur unexpectedly in seemingly robust and healthy girls. In whatever way produced, however, and under whatever circumstances, there is in the generality of, if not in all cases, a predisposition which is potently and emphatically hereditary.

Progressive Pernicious Anæmia.—I only allude to this rare and mysterious affection in order to make the list of affections now under discussion as complete as possible. Unfortunately, so little is known as to the etiology or pathology of this morbid condition that I am unable to furnish any evidence as to whether it can be said to be

hereditary or not. Closely allied *in kind* to ordinary idiopathic or symptomatic anæmia and severe chlorosis, it yet differs materially from either in degree, and is characterised by the so-called "anæmic fever" of Biermer, which, *cæteris paribus*, may be regarded as, to some extent, pathognomonic. Frequently associated with pregnancy, this almost invariably fatal condition sometimes occurs as a complication during ordinary anæmia, but the causes of such complication are completely unknown—as, indeed, is almost everything concerning either its etiology or pathology. At the same time, as it is closely allied to anæmia and chlorosis—which, as we have seen, are both hereditary—I cannot abandon the idea that in some cases, at least, there is an hereditary element in its production; there can, at any rate, be no effect without a cause, and as the causes of disease are either inherited or acquired, I shall at least maintain the hypothesis of heredity, until it can be proved that this mysterious condition is dependent entirely upon external circumstances for its causation.

Corpulence or Obesity.—It must be admitted that a predisposition to this condition is generally either inherited or congenital, and this despite all other causes that can be assigned. Those who are predisposed will become fat under any circumstances, and in any rank or condition of life. Like most hereditary constitutional anomalies, its transmission consists in a tendency only, and it may also be included amongst those affections which occur at corresponding periods of life. Thus it may occur during infancy, or not until the fortieth year or thereabouts, and later. It has not yet been determined whether sex has any influence on the hereditariness of this affection, or whether the male or female parent has most to do with the transmission of the tendency. It is more than probable, however, that the predisposition more frequently descends from and to the same sex—viz., from father to son, and from mother to daughter.

Immermann, in discussing the peculiarities of constitution upon which the inherited corpulence can depend, enumerates the following—viz., hereditary differences in the rapidity of blood formation, dependent upon the new growth of red corpuscles; hereditary differences in the trophic and plastic energy of the other tissues of the body; and hereditary differences in the quantity, function, and proliferating capacity of the fat-carrying connective tissue and its vascular apparatus. The foregoing are some of the conditions which on the one hand influence the extent of the tendency to fat-production; and, on the other hand, possibly or certainly, come under the influence of the hereditary principle. Thus far Immermann analyses the constitutional peculiarities on which, in a pathological sense, corpulence depends; but it will be seen that they are all hereditary, and this is the main point for which I am contending. There cannot, indeed, be any doubt that obesity is a condition, a tendency to which is unquestionably hereditary, and that it characterises families for successive generations *malgre* many systems of treatment and innumerable nostrums, notwithstanding which *natura non nisi parendo vincitur!*

Scrofulosis.—However great the temptation, I have no intention of entering here into a discussion of the innumerable theories propounded from time to time as to the etiology and pathology of scrofula, and its relation to tuberculosis, but shall content myself by observing, in the words of Dr. H. G. Sutton, that "A strumous constitution produces phthisis; scrofula and phthisis are inseparable." Regarding tuberculosis or scrofulosis as a constitutional

disease, it is now universally acknowledged to be hereditary in its origin. Pathologists are divided in their opinions as to whether the disease itself, or a predisposition to it, is inherited; and, notwithstanding the fact that tubercle is often actually congenital, I am inclined to believe, with Niemeyer and his school, that as a rule, only a constitutional debility is transmitted, with a tendency to low forms of inflammation, the products of which rapidly become caseous, and thus lead to tubercle. My own opinion is that a pre-existing condition of scrofula is, in the majority of cases, necessary for the development of tubercle, although what is recognised as scrofulous does not always attain a distinctly tubercular condition. In tubercular as in scrofulous cases, there will usually be found a predisposing as well as an exciting cause—the former being hereditary, the latter acquired; and the higher the degree of hereditary predisposition, the less need there will be for an exciting cause.

Following closely the definitions of Virchow and Billroth, Birch-Hirschfeld thus defines scrofulosis:—A constitutional anomaly which shows itself by changes, partly of an inflammatory, partly of a hyperlastic nature, excited in the tissues by a comparatively slight noxious influence—changes which are endowed with insufficient recuperative power, and are therefore prone to lapse into regressive metamorphosis, and following thereupon, into local tuberculosis. Virchow ascribes scrofulosis to “a certain weakness or incompleteness in the structure of the lymphatic glandular apparatus,” and accepting this theory as far as it goes, we should remember that pathology furnishes us with many proofs as to the dependence of weakness of certain systems and organs on a hereditary predisposition. Thus hæmophilia furnishes an example of inherited weakness in the circulatory apparatus. Many other instances might be mentioned.

Of the causes which give rise to scrofulous constitutions—apart from anatomical and physiological conditions, concerning which nothing is definitely settled—the most important, and that most materially supported by experience, is hereditary transmission. Undoubtedly various forms of scrofulous as of tubercular disease run in families. Every practitioner must be cognisant of the fact that the parents of scrofulous children were themselves, in many instances, also scrofulous in their early age, and that phthisical parents very frequently generate scrofulous children. Although statistics may not count for much, yet Lebert was able to prove hereditary transmission in one-third of eighty-eight cases. Balman ascertained that among 141 scrofulous patients nine had lost the father, and eleven the mother, of tuberculosis; while thirty cases of tuberculosis had occurred in near or distant relatives of the rest.¹ It must therefore be conceded that from first to last, amid all its sources and varieties, amid all its developments and retrogressions, in whatever form it may assume, amid all its degrees and complications, heredity is the prime factor in the production of scrofulosis, as it is also in tuberculosis.

Diabetes Mellitus.—But a few decades ago, anyone who would have ventured to include heredity as a predisposing cause of this affection would have probably been treated with ridicule. Since, however, greater attention has been directed to the matter in more recent times, the result of constantly accumulating experience is undoubted and increasing testimony in regard to the hereditary character of

diabetes. Not only have several of the brothers and sisters in certain families become diabetic, but instances are recorded where every child has been the subject of this disease. Moreover, it has been frequently observed that parents, or grandparents, suffering from the disease, have transmitted a predisposition to their children and grandchildren respectively; nay, more, cases have frequently occurred even among the collateral and more distant relatives of diabetics. I feel assured that time and increased experience are alone wanting to substantiate the views held in the foregoing pages as to the influence of heredity in the production and development of morbid conditions generally, and for the reasons assigned—viz., that the inheritance of physiological and psychological peculiarities necessitates the inheritance of those which are pathological.

Epilepsy, mental affections,² and other diseases of the nervous system are often intimately associated with diabetes, and this connection is also, in almost every case, due to hereditary predisposition. Cases showing the coexistence of epilepsy, melancholia, etc., are recorded by Seegen, Zimmer, Schmitz, and other authorities. Among the near blood relations of a diabetic patient Langiewicz found epilepsy in seven. One of Griesinger's patients had had epileptic seizures in childhood, and all the brothers and sisters had suffered, or were suffering, in the same way. A case is recorded by Lockhart Clarke, in Beale's *Archives of Medicine*, in which diabetes occurred in an epileptic who died of cerebral softening.

As to the heredity of diabetes itself, many cases are recorded by P. Frank, Blumenbach, Brisbane, Prout, Pavy, Dickinson, and Senator, and Marsh records the case of a family in which the disease was transmitted even to the fourth generation. From 1868 to 1874 R. Schmitz was enabled to positively affirm the influence of heredity in 22 out of 104 cases.³

Diabetes Insipidus is also undoubtedly hereditary, and like the mellitic affection is frequently associated with the neuropathic predisposition. An hereditary association has also been observed between the insipid and mellitic variety. Thus Trousseau, Reith, and Seegen report cases in which the grandfather had the mellitic and the granddaughter the insipid form; a father and son had the mellitic and a daughter the insipid form, and a son had diabetes mellitus whose father had suffered from diabetes insipidus. The most remarkable instance of hereditary predisposition is that recorded by Lacombe, in which, out of one family a mother, three sons, and a daughter were attacked by the insipid form of diabetes, besides the brother of the mother and his children. Other interesting and less startling cases are reported by Lancereaux, Deebray, Reith, Desgranges and Addinel Hewson.

Having thus glanced rapidly at the principal general disorders of nutrition, it will be seen that heredity has a large share in their production; and although in some instances the testimony recorded may be less satisfactory than in others, yet I firmly believe that in the future, and probably before long, increased experience will not only attest the views I have enunciated, but will throw the light of science over that which may now appear to be vague and hypothetical.

HEALTH RESORTS OF THE WORLD.

XX.—NOTES ON MADEIRA AND THE CANARY ISLES.

BY ROBERT R. RENTOUL, M.D.

(Continued from page 223).

THE drives and rides about Las Palmas are very fine. Ladies should take their habits, and saddles with good girths, as the Spanish saddles, for both men and women, are far from comfortable. A light waterproof will also be found useful, for sometimes the rain comes down suddenly, although generally it rains here during the night. The scale of charges for the various drives is posted up at the hotel, but the visitor is not bound to accept these, as he can make his own arrangements. One may engage a coach by the week. However, the three-horse coaches cost only about two to three dollars (8s. to 12s.) a day. These carry five persons comfortably, and the cost, divided among so many, amounts to a very small sum. The horses are not very good, and the drivers will, if permitted, use the whip too freely. There are no hammocks or carros here. One wonders, when will hotel enterprise give the visitor the opportunity of having a camel ride. There are a great number of these animals in the islands, especially at Lanzarote, where a camel costs about two and a half pesetas (about 2s. 1d.) a day. Several of the drives and rides may be mentioned:

1. *That to the Isleta, Lighthouse, and Bay of Confital.*—On the way down towards the isthmus and port we pass, on the sea-side, the saline springs of Santa Catalina. A French doctor has written a pamphlet on this water, and gives an analysis. It tastes remarkably like sea-water. The baths are said to be useful for skin affections. Further on is an old Spanish fort, built during the conquest of this island. On the town side the beach is good, while the sea-breeze is fresh and invigorating. Here many invalids, residing at the hotel, drive down each morning, sit for some hours, and have their "sun-bath." They leave their chairs at the little fielato or custom's house, where all passers-by—either on foot or in coach—are stopped, so as to find out if they have any goods on which duty can be levied. The public conveyances, or street coaches drive to and from the fort, and walk about looking for "fares." Their charge up or down is half a peseta (5d.), but they are not comfortable, although one may run down for the "sun-bath" in one. Near to the castle or fort of Santa Catalina, the telegraph cable comes on shore. About here the facilities for bathing are fair; some, however, prefer to bathe off the different moles. The temperature of the sea-water is about 65° F. There are no sharks. Having inspected these points of interest, and driven on to the isthmus, the coach turns off the main road to the left, and follows the road by the shore.

Here we left the coach and followed a narrow path along the cliffs. We passed the Guancho cemetery on our right, and further on, descend on the flat sands; and from here, on the face of the cliffs, some Guancho caves—the houses of the earth dwellers—are seen. It is a steep climb up to these, and the invalid had better not attempt it. Further on the path leads to Confital Point, near to which are the Salt Works. The salt water is pumped into pans, while the hot sun evaporates the liquid. It is said to be too coarse for table use. There is one other salt works at the south end of the island. The view of the Bay of Confital, with the

opposite cliffs, and the curving strand, is very grand; and especially so when the wind is blowing in, when the waves and surf equal anything of its kind seen along our own coast. On the same, or another day, the lighthouse may be visited, or the new pier examined. When the latter is completed there will be a fine harbour; at present, when the wind is high and the sea rough, ships have to anchor in Confital Bay. I think visitors scarcely appreciate this part of the island sufficiently. There is little or no climbing, so it suits invalids admirably.

2. *The Drive or Ride to Telde.*—This takes us through another part of the town. While we advance, the English cemetery is passed on the right, and to the left, but further off the road, is that of the Spaniards. The castle of San Cristobol is seen, and then we come to the tunnel, which is a good piece of work, the passage having been cut through the solid rock. On its town side is a little bay—a good place for having lunch. The rocks on the land side of the road are high and steep. Beyond is the village of Ginamaris, and finally Telde is reached. The public coach runs from Las Palmas to this town. Further on are the towns of Tugenio and Aguimes, while on a line, at right angles to the former, is the Punta de Gando, near which the Spanish steamer Alphonso struck, and from whose hold divers recovered some chests of gold.

On all these excursions Mr. Quiney supplies the lunch free of extra charge. This is put in a basket, and the driver of the coach is generally obliging, and carries it to the spot selected for lunching. Claret, milk, beer, and other beverages are charged for as usual. The visitor will find a knowledge of Spanish very useful. As a rule the coach drivers don't understand a word of English; consequently, if one unacquainted with Spanish wishes to gain any information from him about points of interest, he is quite useless. The Spanish language is easily learned; if one knows thoroughly the first fifty or eighty lessons in Orlandorf, he will get on very well. The "key" to this grammar will help during self-instruction. Bustamente's English and Spanish dictionary, taken about with one, will supply the necessary words when memory fails.

3. *To Atalaya and the Caldera.*—This is a most enjoyable drive. The road leads through Tarifa. Beyond this, and to the right-hand side of the road, is a beautiful spot, called the Glen of Laurels. It is reached by descending a rather steep path. A stream runs through it; this, with the grass and the shade of the tall laurels, making a favourite resort for picnic parties. Having visited this spot, we drove along until the point is reached where the road to Atalaya leads off. This latter is too narrow and rough for driving, therefore, when about to make this excursion, it is desirable to send on donkeys from Las Palmas. Of course, the entire trip may be done on horseback. The ride from the main road to Atalaya takes about thirty minutes. This cave village is placed on the side of a high hill, and from this a panoramic view may be had. Here the people live in caves. They are occupied in making pottery of a coarse kind—one woman completing a large basin while we waited. This, when dried in the sun, is put into a oven when it is fired. Near to the village is a wine shop, where the grape juice is both made and sold.

After returning to the main road the coach drives back a little on the way to Las Palmas, and then turns off to the right, here taking the road to the Caldera. It is a fairly long climb from the foot to the Peak, which is marked on the

Admiralty chart as 1850 feet above the sea level. The view from here, especially of the coast line, is good, while some "natural glass," and other products of volcanic origin, may be picked up. Having climbed the peak, it is well to go down into the Caldera. A small farm is seen at the bottom. Here also is a spring, some fruit trees, and other farm produce. Perhaps some will find that it is well to devote one day to Atalaya, and another to the Caldera, thereby avoiding fatigue and the cold evening air of the mountains. We followed the latter plan.

4. *Agaité and its Mineral Springs.*—To make this trip, either by coach or horseback, one must start about 7 or 8 a.m.; or the public coach to Arucas may convey us to the latter town, having previously ordered that horses be there waiting. Soon the village of Tamaraceite is passed. It should be mentioned that there is a fonda (hotel) at Arucas. The next town is Guia, a distance of about five hours drive from Las Palmas. Here there is a small hotel where the visitor, on the way to Agaité, will sleep at night. Next morning Galdar, its peak and caves, should be visited. After this a start is made for Agaité, and having seen the objects of interest here, the return is made to Guia the same evening. A public coach now runs from Arucas to Guia. The mineral waters of Agaité are chalybeate, and have a temperature of about 77° F. These are highly carbonised, and, according to P. R. Ogle, F.C.S., contain carbonate of iron, lime, magnesia, soda, and silica. There are about 10.0 grs. per gallon of iron. Here there are also bath sheds and baths. What a pity this water is not bottled and sold at the hotels. Agaité is thirty-two miles from Las Palmas, so it is rather a long trip. Some only go the length of Arucas, lunch there, and return in time for dinner.

5. *To Fergus.*—This makes a good day's ride or drive. Starting early in the morning one passes through Arucas, when, after a run of three and a half hours, we arrive at Fergus. There is a fonda here at which a meal, having been ordered the day before, may be had. The waters and baths of Fergus are considered to be beneficial for rheumatism and skin affections. One may either stay in this place or at Arucas all night, or chance a late drive back to Las Palmas. Mr. Quiney has some of this water at his hotel. It tastes something like Apollinaris, contains some lime, magnesia, and soda, while it is slightly aerated. It is, however, badly bottled and wired; but if it were properly treated in the latter respect it would make a fair table beverage. Fergus and Agaité, being at a considerable elevation, are pleasantly cool during the hot summer months. Perhaps in a few years—if the Canary Isles continue to grow in public estimation—good hotels will be established at these places.

6. Another drive is that to Tenor, where there is a church, mineral spring, and convent, as well as the Bishop's Palace. The Bishop of these islands has his head-quarters at Grand Canary. At evening hours he is often seen walking along the road towards Telde, when he gives the passer-by his benediction, a compliment returned by visitors by their lifting their hats.

7. *San Mateo and San Brigada.*—The tobacco factory at the latter place may be visited, and a purchase made. The growth of the tobacco is progressing in these islands. The cigars are usually smoked when green, and the result is that they so irritate the throat as to cause inflammation and perhaps ulceration. San Mateo is celebrated for its chestnuts, while beyond it are some snow wells. In these various rides

or drives a guide need not be taken; but if the visitor wishes to visit the interior of the island, taking his camp and camera with him, a guide will be necessary.

Who should go to the Canary Isles?—This is a question somewhat difficult to answer, as sufficient experience has not yet accumulated. The temperature of these islands, taken at the sea level, is almost uniform, therefore the invalid may move about from one place to another. There are no sudden variations of temperature, although I am told that a chill is likely to be noticed at about 4 to 4-30 p.m. Dr. M. Douglas—to whom the credit of bringing Las Palmas before the medical world, and so through them to their patients—has given the mean lowest temperatures for November, December, January, and February, as 61.0°, 56.1°, 55.6°, and 55.1° F., while the mean daily range for the same periods was 9.7°, 11.0°, 10.4°, and 10.8° F. Occasional showers of rain may fall, this being followed by a brighter sunshine, and a purer atmosphere. The air outside the town is very pure and rarefied, each angle and line of the buildings coming out distinctly and well-defined—an important feature in any atmosphere. There is no smoke to contaminate it, while, during the night, the dew-fall is almost altogether absent. That the climate is good, and the soil productive, may be noted by the fact that the labourer takes three crops off the same piece of land during the twelve months; and also by observing the many delicate flowers which grow outside, as well as the many fruits. Canary birds are occasionally seen in their greenish-yellow plumage, which turns to yellow in captivity. That great class of people who are neither well or ill, but who must winter out of England, will find this a genial climate, returning home about May or June. So will the business man, worried by anxiety, while the cable will keep him informed on any urgent subject. Those suffering from chronic rheumatism, and such like pains, will derive considerable relief. The patient, convalescing from an acute illness, will find the not too bracing sea voyage of seven days out do great good; while the sufferer from consumption will find that the air is warm and sedative, and his cough much less troublesome. Lastly, the tourist will thoroughly enjoy a ramble through these interesting islands. Houses may be taken by the month, the rent of these varying from £3 to £6 (per month). Some prefer to live this way, especially those who have large families. Servants' wages are low, ranging about one peseta per day. They are not, however, bound to give a month's notice before leaving; the result is they may march off when a dinner is being cooked. However, this may prevent ebullitions of temper on the part of the employer to the employed! Almost all foods may be obtained at the English shops, such as the stores of the African Trading Co., and it may be stated generally, that all necessary articles of food are cheaper here than in England. Of course, a visitor will take an Etna, an india-rubber bottle, some preserved soups, and beef extracts. Silver's soups, with fire-wood attached beneath, all ready for lighting, will be found useful by those who take trips into the country, as the food of the Spanish fonda may not be appreciated. One may take a good chart of the island, a good compass, one or two thermometers, and a barometer, if they take any interest in recording temperature, etc.

There are several English physicians, Drs. Cockburn, Fernandez, and Vines. Dr. Don Gregorio Chil is the leading Spanish medical man. British doctors are not permitted to sign death certificates, and the result is that

when an English person may be about to die, a Spanish physician has to be called in. This, however, may in time be rectified, as an English doctor by studying at Madrid may take out the degree of that university. The old barber-surgeons are not yet extinct at Las Palmas. Generally, there is a clergyman at the hotel, so that Church services are held each Sunday at the British Consulate. I believe, however, that an effort is being made to establish one permanently here. The coinage at Las Palmas gives a little trouble at first, but remember a Spanish dollar equals four shillings; a tostone (with two pillars), one shilling; a peseta equals tenpence; a real, twopence halfpenny; and five centimos equal one halfpenny. Many of these are again subdivided into half-pesetas, etc.

It would not be altogether honest if one—after speaking of the advantages of a place—failed to notice its disadvantages. For instance, the mosquitoes are sometimes troublesome, and it has been lately stated that they may be the means of conveying, through the puncture made by them, the active material which may give rise to future trouble. If, however, a good net be used, and a search made for the mosquitoes before going to bed, and if the hands and face be bathed with water, with which a little carbolic acid has been added—just enough to give a taste to the water, before going to bed, little or no inconvenience will come. The net may be also sprayed with water and carbolic. Another unpleasant feature of all the islands—Madeira included—is that fully eighty per cent. of the visitors suffer from diarrhoea. Fortunately, it may pass away in a few days, but some have been so tormented that they have had to leave. For affording such a change, one might hope that a few days at Agaite or Fergus would effect a cure. It is not known what is the cause—water, wine, fruit, and impure air, each and all being blamed. At all health resorts the visitor will avoid crowded rooms, for consumptives seem to think there is a virtue in their inhaling warm impure air. Big hotels for such invalids are, in reality, consumptive hospitals. The Spaniards have a strong objection to nurse consumptive patients, and burn all bedding, clothes, and furniture belonging to the deceased patient.

Hotel accommodation will slowly go on improving as owners continue to derive a profit on their investment. It is to be hoped that a rush of prosperity and success will not make them blind to faults, but that they will take them to heart, and remove all sources of irritation, for Las Palmas is a place of pleasure as well as a health resort. Life here might be made far more enjoyable, and with only a little extra expenditure—and this not on the part of the hotel keepers. Sound practical use might be made of the Agaite and Fergus waters. Hotel proprietors might contract with the military authorities, so that their regimental band would play in the plaza in front of the hotel three times weekly. See the fruitful efforts made at various continental resorts—Carlsbad, for instance. There, there are two taxes put on visitors—the “cure tax” and the “music tax.” The former varies with the social status of the visitor, and ranges from ten to twelve florins, while the latter ranges from eight to ten. The tax for the reading and smoking rooms is two florins per month. And the result is, that in the matter of music, their band of forty-eight performers is one of the best in Europe. Las Palmas should also have an Ice and Aerated water company. It seems strange that in none of these islands is there an Ice company, and that a bottle of soda water costs sixpence. Perhaps chronic invalids, as a class,

do not spend as much money as others; and I suppose it was a feeling born of this thought that prompted an hotel manager to say he “preferred tourists, because they had more money to spend, and because they drank more liquor!” There are no hot-air, or vapour baths.

Grand Canary is in touch with Liverpool, London, Plymouth, Hamburg, and Cadiz. The British and African S.S. Company run steamers weekly, while Forwood's boats leave London monthly. The New Zealand Shipping Company's steamers call at Santa Cruz, while the Union, and Castle lines call at Madeira; Spanish and German lines also call. The British and African Company have secured the Spanish contract for carrying the mails between the different islands of the Canary group. This company say they are determined to make their service of steamers as comfortable as possible, while the local passenger rates are to be lower than they now are. Being under mail contract, regularity should be guaranteed. At the same time they propose building a sanatorium about half-way between the town and the port. This in itself will add greatly to the attractions of Las Palmas. An American hotel has lately been opened, and a large English hotel is to be built a little way out of the town, between it and the port.

Santa Cruz, Laguna, and Orotava.—Santa Cruz has a population of about 15,000, that of Teneriffe being 105,000, while Grand Canary is 90,000. It is the Capital of the Canary group of islands, and here the Governor and the Captain General reside. The people of Las Palmas are anxious that the Government department should be transferred to their island. There is a fair amount of jealousy between these two places, consequently severe statements must be taken with the traditional “grain of salt.”

The view of Santa Cruz from the sea is pleasing—the town stretching along the shore, the square built and flat roofed houses, generally painted white, the forts, the mole, and the spires of the two cathedrals making a foreground, while the mountains behind the town add their share in completing the picture. The mole, or pier, at which the divers are working, is being pushed to completion, and no doubt in the near future will provide such secure shelter that boating exercise may be added to the attractions of this place. The sea, right into the shore, is deep, so that steamers when anchoring must let go a long length of cable. It is said that the holding ground is superior to that at Las Palmas. Various coal hulks and steamers lie in the bay, while during the thirteen days of our stay a British training squadron, a French convict ship, with 300 convicts bound for the New Hebrides, a German gun boat, and various steamers from New Zealand, Cadiz, and England came in. It was strange to watch the Spaniards towing the cattle from the coasting steamers on to the shore.

It is generally an easy matter to land here, but sometimes there is a heavy swell on. At such times passengers are brought on board, from the boat alongside, in a cane chair, this being heaved up by the winch. This is a very agreeable way of getting on board, and at all times so, for weak invalids. It seems to be quite free from risk and danger. It should be mentioned that the managers of the different hotels come on board and receive any passengers who wish to go with them. They will also look after the luggage. There are no custom duties either here or at Las Palmas, although shippers have some duties to pay.

We landed at the mole and walked to the International Hotel, others going to Camacho's. We found our hotel very comfortable—beds clean, food and attendance good

while the bath room was much better than that generally met with out here. The charges are similar to those at the other island hotels, 8s. and 10s. per day; but we heard that the "International" has been bought out, so that the Telegraph Company may have its head-quarters there. There was not a billiard table. At the mole, one is pointed out a stone in the wall which is said to have been struck by a cannon ball when Nelson attempted to storm this town, and when he received that injury which necessitated the amputation of his arm. Like many other defeats in life, little has been accurately stated of this one. However, he attempted a landing, and his boats parting company, all concentration of action was lost; he having, previous to his retiring, "given" two British flags to the Spaniards, who obligingly keep them in two glass cases at the Church of the Conception, where they may be seen on the side wall above a little altar. At the base of the mole is a bathing house.
